**Venous drainage:** About 15–20 veins, after draining the testis and the epididymis, approximate to each other to form the pampiniform plexus which ascends anterior to the vas deferens, and at superficial inguinal ring this plexus joins and form four veins. At deep inguinal ring, they again join and form two veins. Finally single vein is formed in posterior abdominal wall that drains into the inferior vena cava on the right side at an acute angle, and into the renal vein on the left side at a right angle (Datta 2010).

**Lymphatic drainage:** The testes drain into pre-aortic and para-aortic lymph nodes.

**Nerve supply:** The testis is supplied either by nerve fibres that arise from the tenth and eleventh thoracic segments of spinal cord, through the renal and aortic plexuses, or by nerve fibres that arise from the pelvic plexus (Rauchenwald et al. 1995).

The ampulla of the vas deferens unites with the duct of seminal vesicle and form ejaculatory duct. It opens on the verumontanum of prostatic urethra. The seminal vesicle secretes viscid, yellowish-white alkaline fluid and form bulk of semen which is rich in fructose, prostaglandin, and coagulating enzyme vesiculase for nourishing spermatozoa. Ejaculatory duct obstruction due to congenital cysts or urethral injury can cause oligospermia or azoospermia (Standring 2016).

**Vasectomy:** This is the most common method of male sterilization. In this procedure, a small segment of the ductus deferens is ligated and/ or cut out in the upper part of the scrotum (Moore et al. 2014).

### Prostate

The prostate is a conical fibro-muscular glandular organ that encloses prostatic urethra. It is around 20–25 gm in young adult and 30 gm in

old parson. The prostate provides about 30% of the volume of seminal fluid. Its secretion is slightly acidic with a pH around 6.4 which consists of acidic phosphatase, citric acid, fibrinolysin, prostaglandins, prostate specific antigen (PSA), and zinc. PSA liquefies semen, helping in sperm motility and also dissolving cervical mucus (Arneth 2009).

The normal level of serum PSA is 0–4 µg/L. PSA is commonly elevated in prostate carcinoma but in BPH, inflammation, and infarction, PSA level may be increased (Arneth 2009). Zinc protects sperms in female reproductive system. Fibrinolysin liquefies semen. The prostate lies in the lesser pelvis behind the lower part of pubic symphysis and pubic arch. The Prostate is covered by inner true and outer false capsule. The space between these capsules is filled with prostatic venous plexus. The prostatic venous plexus communicates with the internal vertebral venous plexus (para-vertebral vein of Batson), due to this communication prostatic carcinoma can spread to the brain.

### Zonal Anatomy of Prostate

On the basis of the glandular tissue, prostate may be divided into three distinct zones.

1. Transition zone (5% by volume of total glandular tissue) lies around distal part of pre-prostatic urethra. Ducts of transition zone open on verumontanum, just above where the ducts of peripheral zone open into prostatic sinuses. Benign prostatic hypertrophy (BPH) affects transition zone. As transition zone grows, it compresses preprostatic and prostatic part of urethra which leads to anatomical bladder outlet obstruction. It may present as lower urinary tract symptoms, infections, and retention of urine (Patel and Parsons 2014).
2. Central zone (25% by volume) is wedge-shaped and forms base of gland with its apex at verumontanum. It surrounds ejaculatory ducts as they course through the gland. Central zone is rarely involved in any disease process.
3. Peripheral zone (70% by volume) surrounds central zone from behind and below, but does not reach up base; it extends downwards to

form lower part of gland, except anteriorly. Peripheral zone is solely involved in carcinoma of prostate.

#### Age Changes in the Prostate

At birth, prostate mainly consists of system of duct embedded in fibro-muscular stroma. At puberty, the prostate exhibits maturation phase mainly due to follicular development and achieves more than two times of its infant size. During 40–50 years, epithelial folding tends to vanish and follicles contain corpora amylacea (prostatic concretions). After 50 years, the prostate tends to develop BPH.

#### Arterial Supply

The Prostate is supplied by branches of the inferior vesical and middle rectal arteries and internal pudendal arteries.

**Venous drainage:** The veins form the prostatic venous plexus, which lies between the true and false capsule of the prostate. The prostatic plexus receives the deep dorsal vein of the penis and vesical venous plexus and drains into the internal iliac veins. A few vein drain posteriorly into internal vertebral venous plexus which is also known as para-vertebral veins of Batson. This route helps in metastasis of tumour cells from prostate to the vertebrae and brain (Datta 2010).

**Lymphatic drainage:** The lymphatics of prostate drain into internal iliac, external iliac, sacral, and obturator lymph nodes (Standring 2016).

#### Spermatic Cord

It is a tubular sheath-like structure, which begins at the deep inguinal ring and exits at the superficial inguinal ring. The spermatic cord contains vas deferens, testicular artery, pampiniform plexus of veins, and lymphatics and nerve supplying the testes, all these structures lie within the internal spermatic fascia. Besides these, the spermatic cord includes ilioinguinal nerve, genital branch of the genitofemoral nerve, the cremasteric artery, veins and lymphatics, and artery to vas deferens, veins, and lymphatics which are confined within the external spermatic fascia.

#### Penis

The penis is the male organ of copulation. It consists of a root or attached portion or radix and a body (shaft) or free portion.

The root consists of two crura and median bulb of penis. The body of penis is composed of three elongated masses of erectile tissue: a pair of corpora cavernosa on the dorsum and unpaired corpus spongiosum containing the urethra on the ventral surface. Each corpus cavernosa consists of cavernous spaces which are lined by the endothelium. During erection, blood flow increases and these spaces are filled with blood, leading to penile engorgement and compression of venous outflow channels.

**Arterial supply:** The penis is supplied by the bulbourethral artery, the dorsal penile artery, and the cavernous (deep, cavernosal) artery which are terminal branches of internal pudendal artery (Standring 2016).

**Venous drainage:** The penis is drained by the superficial and deep dorsal vein. The superficial receives blood from the prepuce and skin and drains into great saphenous vein. The deep dorsal vein ultimately drains into the prostatic venous plexus.

**Lymphatic drainage:** The penile and perineal skin is drained into the superficial inguinal lymph nodes. Lymphatics from the glans penis drained into the deep inguinal and sometimes into external iliac nodes and those from the erectile tissue and penile urethra drain to the internal iliac nodes.

The erection of penis is vascular phenomenon which is controlled by parasympathetic nerves (nervi erigentes, S<sub>2-4</sub>). In emission process, semen is transported to the prostatic urethra by the ejaculatory ducts, which is under control of the sympathetic nerve (L<sub>1-2</sub> nerves). Ejaculation is discharge of seminal fluid from the prostatic urethra to outside of body which depends on both autonomic and somatic nerve and includes closure of the internal urethral sphincter under sympathetic effect (L<sub>1-2</sub> nerves), contraction of the urethral muscle by the parasympathetic response (S<sub>2-4</sub> nerves), and contraction of the bulbospongiosus muscles with the help of pudendal nerves (S<sub>2-4</sub> nerves) (Moore et al. 2014).

Developmental anomalies:

1. **Phimosis:** It is a condition in which the prepuce is elongated and covers partially the external urethral opening. Surgical circumcision is the treatment.
2. **Epispadias:** In this condition, urethral meatus is found on the dorsum of the penis (Sadler 2015).
3. **Hypospadias:** In this condition, there are abnormal openings of the urethra along the ventral side of the penis (Sadler 2015).
4. **Micropenis:** It occurs due to insufficient androgen stimulation.
5. **Bifid penis:** It occurs due to splitting of the genital tubercle (Sadler 2015).

## Female Reproductive System

The female reproductive system comprises uterus, uterine tubes, and ovaries (the upper genital tract) and the vulva and vagina (lower genital tract).

### Uterus

The uterus is thick walled, hollow, muscular, and inverted pear-shaped structure. It is situated in the lesser pelvis between the urinary bladder and the rectum. Superiorly, it opens into the uterine tube and inferiorly opens into vagina.

### Subdivisions

The uterus is subdivided into two parts from superior to inferior: muscular body (corpus uteri) and fibrous cervix (cervix uteri). The ratio of body: cervix length is 2:1 in adult, whereas, 1:2 in infant. The body extends from the fundus to a constriction which is called isthmus (internal os of cervix). The part of the body which lies above the opening of uterine tube is called fundus.

### Axes of Uterus

In the adult nulliparous state, uterus lies in anteversion and antelexion. Anteversion is forward tilting between the axis of cervix and the axis of vagina which is around  $90^\circ$ . Antelexion is forward tilting between the axis of cervix and the axis

of body which is around  $125^\circ$ . In 10–15% of women, the uterus is retroverted in which uterus leans backwards at an angle to the vagina and is called retroverted. When the body of uterus leans backwards at an angle to the cervix, it is called retroflexed (Standring 2016).

### Body of Uterus

Body is flattened antero-posteriorly, so it has two surfaces – anterior and posterior, and right and left lateral borders, and a uterine cavity. Anterior surface is flat which is lined by peritoneum up to isthmus and after covering up to isthmus it goes on to the superior surface of the bladder, creating a space between uterus and bladder which is known as utero-vesical pouch. Posterior surface is convex and covered by peritoneum up to posterior fornix of vagina, after that it reflected on rectum and forming rectouterine pouch (pouch of Douglas). Each lateral border is rounded and non-peritoneal and gives attachment to the broad ligament. The uterine artery enters in broad ligament through the lateral border and supplies the uterus. The lateral angle of this border gives attachment to three structures: uterine tube, round ligament, and ligament of the ovary. The round ligament of uterus is attached antero-inferior to the tube, whereas the ligament of ovary postero-inferior to the tube. The cavity of the uterine body is triangular in coronal section, base of which is formed by an imaginary line between the opening of uterine tubes and apex is formed by internal os of the cervix. The implantation commonly occurs in the upper and posterior wall of uterine cavity in the midsagittal plane (Kim and Kim 2017).

### Cervix of Uterus

In nulliparous woman, cervix is more cylindrical and narrower than body of uterus. The cervix is a fibrous structure which consists of mainly collagen and small amount of smooth muscle and elastin (Snell 2017). Its lower part continues into the upper part of the vagina at the external os. Thus, the cervix is divided into two parts: (a) upper supravaginal (b) lower vaginal part. The cavity of the cervix is fusiform on coronal

section, communicating with the body of uterus through the internal os and that of the vagina through the external os. In nulliparous women, the external os is circular aperture, whereas in multiparous it looks like transverse aperture with anterior and posterior lips (Standing 2016).

The wall of the body of the uterus consists of three coats or layers:

- Perimetrium: It is outer serous coat or visceral peritoneum and consists of a mesothelium and a thin layer of connective tissue.
- Myometrium: It is thick muscular layer in which branches of the blood vessels and nerves, supplying uterus are present. It is continuous with muscular layer of fallopian tube, vagina, and true ligaments. It acts as the “living ligature of the uterus” because this layer helps in halting bleeding during menstruation and placental separation by muscular contraction (Datta 2010). During the menses, myometrial contractions may produce cramping.
- Endometrium: It is inner mucous coat and consists of epithelium and lamina propria. During reproductive life, it consists of outer basal layer or stratum basale and inner functional layer or stratum functionale (Pawlina 2016). The stratum basale is retained during menstruation and helps in regeneration of stratum functionale. The stratum functionale is sloughed off in each month with uterine bleeding.

#### Ligaments of Uterus

There are two types of ligament: false and true ligaments. False ligaments are made up of peritoneal folds whereas the true ligaments consist of fibrous and muscular component which mainly provide support to the uterus.

False ligaments are: (1) Broad ligament, (2) Uterovesical fold, and (3) Rectovaginal fold.

True ligaments are: (1) Round ligament, (2) Uterosacral ligament, (3) Transverse cervical, and (4) Pubocervical ligaments.

**Broad Ligament:** These are the folds of peritoneum that extend from the lateral border of the uterus to the lateral pelvic wall on each side. The broad ligament is subdivided into mesosalpinx, mesovarium, mesometrium, and suspensory

ligament of the ovary. Mesosalpinx is the upper part of broad ligament which is attached between the uterine tube and the ovary with the ligament of the ovary. Mesometrium is the inferior part of broad ligament which lies below ovary and the ligament of ovary. Mesovarium is the fold of posterior (or upper) layer of broad ligament. It acts as hilum of the ovary. Infundibulo-pelvic ligament is (suspensory ligament of the ovary) attached between the infundibulum of the tube and the upper pole of the ovary and the pelvic brim.

**Contents of the broad ligament:** The broad ligament contains the following structures:

1. The uterine tube except the intra-mural part.
2. The round ligament of the uterus (proximal part).
3. The ligament of the ovary.
4. Two vessels: the uterine and ovarian vessels.
5. Two plexuses of nerve: uterovaginal plexus and ovarian plexus.
6. Three embryological remnants: epoophoron and its duct (Gartner's duct), paroophoron. Vesicular appendices.
7. Other structures: lymphatics and fibroareolar tissue.

#### True ligaments

1. Cardinal ligaments (transverse cervical or ligaments of Mackenrodt) extend from the lateral part of cervix and the fornix of the vagina to the lateral pelvic walls. The ureter and uterine artery traverse the cardinal ligament.
2. Utero-sacral ligaments pass from the sides of the cervix to the third sacral vertebra. They are palpable during per rectal examination.
3. Round ligament- Each round ligament extends from the lateral cornu of the uterus through the broad ligament to enter the deep inguinal ring lateral to the inferior epigastric artery and attaches distally in the ipsilateral labia majora conventionally. But in a cadaveric dissection study, some researchers found three types of distal attachments: in the first type, the round ligament ended just outside the superficial inguinal ring in more than half cases; in the

second type, before the deep inguinal ring; and, in the third type, under the pubic bone. They didn't observe distal attachment of it at labia majora in any cases (Bellier et al. 2018).

4. Pubocervical ligament passes forward and lies between cervix and posterior surface of the pubic bones.

#### Support of Uterus

##### A. Primary Support

1. Muscular or active: (a) pelvic diaphragm, (b) urogenital diaphragm, and (c) perineal body.
2. Fibromuscular or mechanical: (a) uterine axis, (b) round ligament of the uterus, (c) pubocervical ligament, (d) uterosacral ligament, and (e) cardinal ligament.
3. Visceral: (a) Urinary bladder (upper surface) and (b) Vagina (posterior wall).

##### B. Secondary Support

- (a) Broad ligaments, (b) Uterovesical fold of peritoneum, and (c) Rectovaginal fold of peritoneum.

#### Arterial Supply and Venous Drainage of Uterus

The uterus is mostly supplied by the uterine arteries and partly by the ovarian arteries. The uterine veins form a uterine venous plexus on lateral side of cervix which mainly drain into the internal iliac veins.

#### Lymphatic Drainage

The lymphatic drainage of the uterus is very important because uterine tumour metastases occur through lymphatics.

1. From fundus and upper part of the body: Majority of the lymphatic vessels drain into pre- and para-aortic lymph nodes. But a few lymphatic vessels from the lateral angle of the uterus drain into superficial inguinal lymph nodes.
2. From the lower part of the body: The lymph vessels drain into external iliac nodes.
3. From cervix: On each side, the lymph vessels drain in three directions:
  - a) Laterally, the lymph vessels drain into external iliac and obturator nodes, few of

these vessels drained by para-cervical lymph nodes.

- b) Postero-laterally, the lymph vessels drain into internal iliac nodes.
- c) Posteriorly, the lymph vessels drain into sacral nodes.

#### Nerve Supply

The uterus is supplied by both sympathetic and parasympathetic nerve. The sympathetic fibres are derived from neurones in the T<sub>12</sub>–L<sub>1</sub> spinal segments. The sympathetic fibres cause contraction of uterus and vasoconstriction. Pain fibre from body of uterus is carried by sympathetic sensory fibres. The parasympathetic fibres are derived from neurones in S<sub>2–4</sub> spinal segments. The parasympathetic fibres inhibit the uterine muscles contraction and cause vasodilatation. Pain fibres from cervix are carried by parasympathetic sensory fibres. But all these uterine activities are mostly under hormonal control.

#### Clinical Correlation

1. Cervical carcinoma: It is the most common cause of death among cancerous women in developing countries. It is the second most common cancer effecting women of age group 15–44 years (Sreedevi et al. 2015). It is uncommon in early 20 years of age (Sreedevi et al. 2015). In 70% of patients, Human papilloma virus (HPV-16, HPV-18) is associated with cervical carcinoma. In about 80% cases, cervical cancers are squamous cell carcinoma and related to sexual activity (Shrestha et al. 2018).
2. Fibroids/leiomyomas of uterus: These are the most common benign tumours in women which arise from the uterine smooth muscle tissue (Sohn et al. 2018).
3. Endometriosis: It is defined as the presence and proliferation of ectopic endometrial glands and stroma-like lesions outside the endometrial cavity of the uterus. The most common sites of pelvic endometriosis are the ovaries, fallopian tube, uterine ligament, and rectouterine pouch (Alimi et al. 2018).
4. Prolapse of uterus: In this condition, the uterus herniates into or beyond the vaginal cavity due

to weakness or injury of fibromuscular supports of the uterus. Major risk factors for prolapse are old age, multiparity, high body mass index, constipation, family history, etc. (Doshani et al. 2007).

### **Uterine (Fallopian) Tube**

The uterine tubes are a pair of ducts in which medial end are attached to superior angle of lateral border of the uterus and lateral end communicates with the uterine cavity through its ostium. Main function of fallopian tube is to transmit ova to the uterine cavity after collecting from the ovaries. The two uterine tubes are each about 4 inch. (10 cm) long and lie in the upper free border of the broad ligament of the uterus. The tubes extend laterally from the superior angle of the uterine cavity and open into the peritoneal cavity near the ovaries. Each tube consists of four main parts: intramural, isthmus, ampulla, and fimbria. Intramural (Interstitial) part (1 cm long and 0.7 mm wide) lies within the wall of the uterus. It traverses the uterine wall at the junction of fundus and body. Isthmus (2.5–3 cm long and 1–5 mm wide) is round and cord-like due to thick muscular wall and continuous laterally with ampulla which is the widest part with 1 cm diameter. Ampulla (5 cm long) is the longest, thin walled, and tortuous part of the uterine tube. It is usually the site of fertilization of ovum. The ampulla opens into a trumpet-shaped infundibulum (1 cm long) at the abdominal os. Fimbriae, numerous mucosal finger-like folds 1 mm wide, are attached to the circumference of the infundibulum. One fimbria longer and more deeply grooved than the others is closely applied to the tubal extremity of the ovary and is called an ovarian fimbria. At the time of ovulation, the fimbriae swell and dilated due to engorgement of the vessels in the lamina propria, which helps in capture of the released oocyte.

**Arterial supply:** The fallopian tube is supplied by two arteries – ovarian and uterine arteries. Usually the medial two-third of the tube is supplied by the uterine artery and lateral one-third by the ovarian artery.

**Venous drainage:** The veins correspond to arteries, thus venous blood is drained by the ovarian and uterine veins.

**Lymphatic drainage:** The lymph vessels follow the uterine vein drain into internal iliac lymph nodes and the lymph vessels follow ovarian vessels drain into the para-aortic lymph nodes.

**Nerve supply:** The tubes are supplied by both sympathetic and parasympathetic fibres. The sympathetic fibres are derived from ovarian and superior hypogastric plexuses. The preganglionic sympathetic fibres are derived from the T<sub>10</sub>–L<sub>2</sub> spinal segments. The preganglionic parasympathetic fibres to the lateral part of the tube are derived from the vagus nerve and to the medial part from the pelvic splanchnic nerves (S<sub>2-4</sub> spinal segments).

### **Clinical Correlation**

**Salpingitis:** It is an infection and inflammation of the uterine tubes which is mainly caused by sexually transmitted micro-organism. It is the most common cause of tubal block leading to subfertility and infertility in female (Owhor et al. 2019). The patency of tubal block is tested by the Hysterosalpingography in which radiopaque substance (e.g., Lipiodol) is injected into the uterus by a suitable canula. If tubes are patent, the contrast medium spills into the peritoneal cavity.

**Tubectomy:** This is the ideal method of family planning in female. In this procedure, each fallopian tube is ligated at two points and between the ligatures, the segment is resected.

### **Ovaries**

The ovaries are paired gonads which are homologous of testes in the male. The main function of ovaries is to produce female gametes (oocytes). The ovaries are like almond in shape with dull white colour. In nulliparous, each ovary located in the ovarian fossa which lies on the lateral pelvic wall. They are suspended in the pelvic cavity with the help of the mesovarium. Initially, the ovaries have smooth surface, but post-puberty they become nodular.

**Peritoneal and ligamentous supports of the ovary**

1. Infundibulopelvic (suspensory) ligament: It connects upper part of lateral surface of the

ovary to the lateral pelvic wall. The ovarian vessels and nerves pass through it to reach the hilum of ovary.

2. Ovarian ligament (ligament of the ovary): It lies between uterine end of the ovary and the lateral angle of uterus.
3. Mesovarium: It helps in attachment of the ovary to posterior surface of the broad ligament.

**Arterial supply:** The ovarian artery, which arises from the abdominal aorta, supplies the ovary.

**Venous drainage:** The right ovarian vein drains directly into the inferior vena cava, whereas the left ovarian vein drains into the left renal vein.

**Lymphatic drainage:** The lymphatics from the ovary drain into the pre-aortic and para-aortic lymph nodes.

**Innervation:** Ovaries are predominately supplied by the sympathetic fibres. The preganglionic sympathetic fibres are derived from T<sub>10-11</sub> spinal segments.

#### Clinical Correlation

**Ovarian cancer:** It is the sixth most common cancer worldwide affecting women in developed countries. It is the most fatal of all gynecological carcinomas (Modugno and Edwards 2012). Majority of ovarian cancers arise from neoplastic changes in the surface epithelium. Sometimes tumour cells from the abdominal organs undergo transcoelomic migration and produce secondary ovarian tumour, this type of metastatic ovarian tumour is known as Krukenburg's tumour.

#### Vagina

The vagina is a female organ of copulation. In front, it is bounded by the bladder and urethra while behind it is related with rectum and anal canal. The anterior wall is shorter than the posterior wall. The length of anterior wall is 7.5 cm, whereas length of posterior wall is 9 cm.

**Fornices of vagina:** The circular area of vaginal lumen around the cervix is called fornix of the vagina. The fornix of vagina is divided into four parts: a) anterior fornix, b) posterior fornix, and c)

two lateral fornices. The posterior fornix is about 2 cm deeper than the anterior fornix.

**Arterial supply:** The vagina is supplied by (1) vaginal artery which is a branch of the internal iliac artery, (2) Vaginal branch of uterine artery, (3) Internal pudendal artery, (4) Middle rectal artery, and (5) Inferior vesical artery.

**Venous drainage:** The veins of the vagina drain into the internal iliac veins through the vaginal veins.

**Lymphatic drainage:**

The lymphatics of vagina are divided into three groups:

1. From upper third of vagina: lymphatic vessels drain into internal and external iliac nodes.
2. From middle third of vagina: lymphatic vessels drain into internal iliac nodes.
3. From lower one-third (below the hymen): lymphatic vessels drain into the medial group of superficial inguinal nodes.

#### External Female Genital Organs

The female external genitalia (or vulva/pudendum) consists of mons pubis, labia majora, labia minora, clitoris, vestibule of the vagina, bulb of the vestibule, female urethra, and ducts of the paraurethral and greater vestibular glands.

**Mons Pubis:** It is a round, conspicuous, adipose tissue over the pubic symphysis and pubic bone. Before puberty, the mons pubis is relatively flat and hairless. In adult, it becomes prominent with coarse pubic hair and atrophies slightly after menopause. It is commonly absent in the male.

**Labia Majora:** These are broad, prominent, longitudinal fold of skin filled with subcutaneous fat and loose connective tissue which extend back from the mons pubis to the perineum. Two labia majora join anteriorly and form anterior commissure. Posterior commissure does not join, but merges into neighboring skin and forms ridge which overlies the perineal body. They form posterior limit of vulva. They are homologues of the two halves of the scrotal sac. Subcutaneous smooth muscle in them is homologue of the dartos muscle. The round ligament of the uterus may end in adipose tissue and skin in the anterior part of labium majora.

**Labia Minora:** These are thin elongated cutaneous folds and situated medially to labia majora. There are no fat and hair within these folds. The cavity between the medial surfaces of the labia minora is called Vestibule of vagina. The fold formed by union of labia minora behind is known as Frenulum of the labia (Fourchette). Prepuce or hood of the clitoris is formed by the upper folds of the labia minora over the clitoris. Frenulum of the clitoris is formed by the lower folds of the labia minora under the clitoris.

**Clitoris:** It is homologous of the penis in male. It is not traversed by the urethra. It has a root, a body, and a glans. It consists of two erectile bodies called Corpora cavernosa. Corpora cavernosa is attached to the ischiopubic ramus by a crus that extends from root of clitoris. They unite in midline to form the body of the clitoris. Glans or Tip of the clitoris is a small, round tubercle of spongy erectile tissue at end of body and connected to bulbs of vestibules by thin band of erectile tissue. It is richly supplied with sensory nerve endings.

**Vestibule of Vagina:** It is a cavity between the medial surfaces of the labia minora. It contains urethral orifice anteriorly and vaginal orifice posteriorly. The vaginal orifice is incompletely covered by hymen. In addition to the above openings, it also contains the openings of greater vestibular glands (of Bartholin), lesser vestibular glands, and paraurethral glands (of Skene).

**Bulbs of Vestibule:** These are pair of elongated mass of erectile tissue which are located on each side of vestibule. Each bulb is a homologue of half of the bulb of the penis. Anterior end joined by a commissure and to clitoris by slender band of erectile tissue. Posterior end are expanded and are in contact with greater vestibular gland. They are covered superficially by bulbo-spongiosus muscle posteriorly. They do not surround the urethra. Their deep surfaces contact the inferior aspect of perineal membrane.

**Greater Vestibular Glands (Bartholin's Gland):** They are small, round, reddish-yellow bodies, mucous secreting gland. They are located at the posterior pole of the bulbs of the vestibule. They are homologues of male bulbo-urethral glands. Their duct open into vestibule by a 2-cm long duct, situated between hymen and labia minora (5 and 7 o'clock).

## Introduction

Reputation is based on two things: behavior plus an audience. In its most basic definition, “reputation” is an information source (Russell 2016). Any episode of animal behavior is a potential signal to another animal (Danchin et al. 2004), even if that signal was not a deliberate intention to communicate.

Consider the example of territorial urine marking in mice. When a mouse urinates in your house, that urine deposit is a meaningful signal for other mice (Hurst 2005). In many animals, scent marks have an important role in social communication, allowing “recognition of group members and kin, the advertisement of territory ownership and social dominance, assessment of the quality of competitors and potential mates, and the advertisement and control of reproductive status” (Hurst 2005, p. 220). After a mouse deposits urine, the scent stays behind in the absence of the signaler, detectable by other mice passing near.

The scent mark is more than two-way communication. It is a form of “broadcast signal” or “advertisement” (Hurst 2005). In territorial scent marking, the dominant male repeatedly urinates at a high rate (which keeps the scent strong) within a given spatial area (Hurst 2005). The urine provides information about the identity of the absent depositor and pins that identity to a geographic location. The scent marks provide information for females (which helps them to assess the quality of the territory holder as a potential mate) and for other males (which helps them assess the dominance of that male and therefore whether he should be challenged or avoided).

Social information is abundant in the lives of most animals. Whenever they flock, herd, swim or fly together, or merely coexist within the same area, they have ample opportunity to witness the behavior of others (Danchin et al. 2004). The field of “public information” is the source material for reputation. For example, in territorial bird species (see McGregor 1993), males monopolize a finite territory, bordering territories occupied by other males. In this setting, vision is useful in direct encounters with other males at close range – but there is also auditory communication which allows “learning at a distance” about the activities of other birds. Thus, a male might hear a fight between two unseen males, the outcome of which allows the male to gain “inadvertent social information,” such as the identities of winners and losers of a fight (Danchin et al. 2004; McGregor 1993; Mennill and Ratcliffe 2004). In everyday language, we often hear the word “reputation” as a human-only concept, referring to information conveyed through language-based gossip: where people tell stories about other people (Haviland 1977). To understand reputation in animals, we can approach the topic in two ways: (1) looking from the *human* concept or (2) looking from studies of social eavesdropping in animals. There are three sections below. The first will cover the human concept of gossip and reputation and then compare it to animal capabilities. The second section is on social eavesdropping research. The final section is on the role of reputation in the evolution of cooperation in humans and animals.

## The Human Concept of Reputation

Human definitions put emphasis on morality and character (Morris 1999), with a main focus on gossip (Dunbar 2004). Consider the classic ethnographic work of Haviland (1977), a detailed examination of human reputation. Haviland studied gossip networks in a rural area of Mexico (Zinacantán region), consisting of people living in dispersed hamlets and making a living through agricultural and other types of work. Here, the flow of gossip was highly clustered within local neighborhoods (geographically separated clusters of hamlets). Most people stayed in their own neighborhoods and therefore gossiped mostly on local people and events. However, some people had reason to travel, either for work (seasonal jobs), for political reasons (attending meetings), or for trade (e.g., farmers selling corn at market). This allowed opportunities to gossip with people from other neighborhoods and to learn gossip from faraway. Zinacantán was thus a mix of people with many different sizes of gossip network, depending on residence, livelihood, and travel opportunities. Haviland (1977) also made a detailed analysis of the *content* of gossip, which always took the form of “A tells B about an absent C” (p. 28). There were three stages: (1) *identifying* the person being gossiped about (e.g., if not known personally, then that person’s position on a family tree was discussed: e.g., “he’s the son of . . . who lives in . . .”), (2) telling a *story* about an event (e.g., “[he] went to borrow money from him,” p. 117) and that person’s behavior in the event (e.g., “they say he got angry right away,” p. 117), and (3) *evaluation* of personality (e.g., “He is foolishly ill-tempered,” p. 128). These three stages (identification, story, evaluation) were recurrent over all gossip; but sometimes the stories were heavy on interpretation. For example, one bit of gossip was: “I can tell from the way he slammed the door that he fought with his wife and is now probably going out to get drunk” (p. 175) – a statement that provides not only a description but an interpretation, a conjecture on why it occurred, and a prediction of what that person will do next.

As illustrated in the slamming door example, human gossip is often focused on behavior which deviates from societal rules. How do you define “rules”? According to philosophers (see Haviland 1977, pp. 148–170), rules are socially agreed-upon guidelines for future behavior, assessment of behavior, and role expectations. Haviland (1977, p. 74) provided a catalogue of the most common gossip themes in Zinacantán, and topping the list are (sometimes grim) stories of sexual transgression, drunkenness, divorce, fighting, illegal activities, and various other conflict. The observed rule-breaking focus of gossip led Haviland (1977) to characterize gossip as an essential component of being a citizen in a society: being able to gossip shows knowledgeability not only of the language but of cultural rules. Furthermore, Haviland (1977) proffered that gossip not only consists of reports of rules but helps to define the rules themselves: when gossipers gossip, the evaluative stage of the conversation can be an elaborate shared analysis of a focal person’s behavior and how that behavior compares against acceptable social norms/rules – which, if necessary, leads to a redefinition of the range of acceptable behavior (e.g., if someone broke a rule but had a perceived justification for doing so). Haviland (1977) defined reputation as the accumulated knowledge, shared by many, of a person’s behavior, and how that behavior is judgeable against cultural rules. Seemingly, the human definition of gossip and reputation – as illustrated by Haviland (1977) – is incompatible with the abilities of animals. There are two main barriers.

The first barrier is the lack of explicit cultural rules. As illustrated by Haviland (1977), gossip is often a “report of rule breaking.” Lacking language, animals cannot discuss the rules, communicate the rules, redefine the rules, come to agreements about rules, nor morally evaluate others with respect to these rules. This does not mean that animal societies lack rules (think of the “rules” of dominance hierarchies in primates), but in animals, the rules are nonverbal, and in humans, the nonverbal rules are overlaid with language-based codification and organized justice (Tennie et al. 2010). We can ask whether animals have an innate sense of justice – that which would

allow animals to understand “rule breaking” in the first place. Human justice systems are predicated on *fairness* (Rawls 1958): the notion that an individual should benefit only to the extent that others do not suffer a reduction of benefit. Nonhuman animals do seem to have notions of fairness (see Brosnan and de Waal 2012), particularly as shown in “inequity aversion” experiments where a focal animal A has been shown to react negatively to disadvantageous inequity (“A observed that B received more than A; therefore, A reacts negatively”) and, to a lesser extent, to advantageous inequity (“A observed that A received more than B”). This implies that animals can understand rule breaking to some extent.

Another important part of human justice is the punishment of unfairness. Some animal studies appear to show some form of proto-justice. Aureli et al. (1992) investigated apparent “revenge” incidents in the aftermath of aggressive incidents among Japanese macaques, with two important results. One was that losers in a fight (the victims), being negatively aroused, subsequently engaged in “kin-oriented redirection”: having lost the fight against an aggressor, the victim attacked a more vulnerable member of that aggressor’s family. Their second important result is that these redirections occurred in contexts where the original aggressor was unlikely to intervene. For example, the victim would attack the kin member as part of a group. In that situation, the original aggressor would avoid intervening to defend its kin because of the high probability of injury in fighting a group. This kin-targeted “revenge” often happened in full view of the original aggressor. Observability played a key role in these events: “public information” allowed the macaques to accumulate knowledge about the kin relationships of others (which parallels with our above example from Haviland 1977: “he’s the son of. . . who lives in. . .”) and furthermore allowed the macaques to observe aggressive incidents between others. Thinking about this case of kin-oriented redirection, we can attempt to draw parallels to the three stages of gossip as identified by Haviland (1977): “identification, story, evaluation” (occurring in some nonverbal form among the macaques).

The second barrier is language. Although animals have complex communication systems, their systems are missing features of language (Fitch 2010) which would enable gossip. As Haviland (1977) described it in Zinacantán, information flowed according to human patterns of geography and mobility. Animals also have geography and mobility constraints. We can think back to the examples of territorial urine marking in mice (Hurst 2005) and social eavesdropping in territorial birds (McGregor 1993). In each example, detection of a broadcast signal depended on travel. A mouse needed to be inside a territory to smell its local urine. A bird needed to be within earshot of an aggressive encounter to learn the identities of winners and losers. A signal can reach only so far. Compare this to human reputational signaling. Thinking back to the slamming door example of Haviland (1977), the door slammer’s action is a signal whereupon gossip was a mechanism of broadcast. Even though it probably occurred in front of only one person, the door slamming was “broadcast” in the sense that a gossip verbally reported this event to a wider audience. It is unlikely that the door slammer intended his behavior to be widely known. Instead, his behavior was a symptom of his emotional state (negatively aroused after quarreling). In the internet age, the reach of a reputational signal can be global, enduring, and limitless (Tennie et al. 2010).

In animals, the lack of language ability is a major constraint on the reach of the signal. Mouse B might sniff a urine deposit and learn about the dominance of mouse A (the territory holder), but mouse B cannot subsequently convey that precise message to mouse C who is outside the territory and cannot smell the signal firsthand. The message ends at the perceiver and travels no further. Maynard Smith and Harper (2003, pp. 121-122) partitioned reputation into three “channels” of reputational information:

1. Direct reputation
2. Indirect reputation
3. Reported reputation

Humans have access to all three – but animals only have two (Russell 2016). Direct reputation refers to information gained from any type of one-on-one encounter. Reported reputation refers to gossip. The middle channel – indirect reputation – refers to information gained through pure observation.

## The Social Eavesdropping Paradigm

The basic design of an eavesdropping paradigm has two parts: (1) the study animal is allowed an opportunity to witness playacted or simulated events (“public information”) and (2) the animal’s behavior is measured as an assessment of whether the animal was influenced by the witnessed events. There have been many social eavesdropping studies in recent years (see Abdai and Miklósi 2016; Anderson et al. 2017, Herrmann et al. 2013; Tennie et al. 2010) – but, in fact, the basic design has deep historical roots. Going back decades to studies of animal learning, there are numerous experiments on “observational conditioning” and “observational learning” (Heyes 1994), where a focal animal is allowed an opportunity to view an interaction between another animal and some stimulus; and then the focal animal’s behavior is measured. Classic examples of this paradigm (reviewed in Heyes 1994) are observational conditioning where monkeys learned to fear a snake by observing the fearful interaction between another monkey and the snake and observational learning where a budgerigar learns how to open a covered food dish by observing another budgerigar successfully open the food dish. In observational learning, the focal animal observes the model engage in “action-upon-an-object.” In the chimpanzee study of Hirata and Morimura (2000), the object was a “honey bottle” located within a room with a scattered selection of 20 tools, only some of which were usable for extracting honey from the bottle. They first trained chimpanzee models to use the tools correctly. Then, they allowed other chimpanzees (who were naïve to the task) to observe the models. They found that observer chimpanzees did pay close attention to the model

chimpanzees as a guide for extracting the honey, using tools that models had used – and they paid particularly close attention to the model after their own previous efforts had failed. This study showed that animals are very observant when watching a model perform “action-upon-an-object” (watching the chimpanzee model extract honey). The social eavesdropping paradigm is much the same, except that, in contrast, it involves “action-upon-an-agent.”

Mennill and Ratcliffe (2004) conducted a social eavesdropping experiment modeled closely on the example of eavesdropping territorial birds (cf. McGregor 1993). They studied black-capped chickadees, testing actual territorial males in the wild. They determined the dominance of each male within each flock, using a variety of measures involving males chasing or supplanting other males, or showing resistance, or avoidance, or being observed to adopt a submissive posture. The male’s position in the dominance hierarchy was a key variable. The procedure involved a playback experiment. The investigators obtained recordings of chickadees from a sound library, altered them slightly for uniformity, and then set up a series of opportunities for focal birds to hear the recordings. They began the procedure by luring the focal male to within 5 m of the speaker by playing a chickadee “flock-rallying call.” Then, when the focal male was close enough, they introduced a completely new set of calls that simulated the sounds of territorial males. In the recording, the investigators made one male sound dominant over the other by simulating an episode of “countersinging,” which refers to a situation where one male overlaps his call over another male. Countersinging is a sign of aggression, with the overlapping male perceived as dominant. The investigators gave each focal male the opportunity to learn which of the two male “intruders” was dominant. The final phase of each trial was an assessment of the focal male’s approach behavior after hearing these playbacks. Results differed according to the focal male’s position in the dominance hierarchy. High-ranking males almost all approached the overlapping (dominant) speaker, whereas the low-ranking males approached the overlapping speaker less often, sometimes

approaching the overlapped (subordinate) speaker or not approaching at all. This study showed that some focal males used reputation to learn the dominance of previously unknown (in this case, fictional) males.

Another bird study is from Ophir and Galef (2003), who used the social eavesdropping paradigm on Japanese quail. They allowed female quail to observe aggressive interactions between pairs of males. The procedure consisted of two phases. The first was the fight phase, where females observed males pecking at each other across a transparent partition. The winner of the fight was determined as the male that pecked more often. The second phase was a choice phase, where a barrier was lifted, allowing the female the opportunity to approach either the winner or the loser (although these males were still behind a transparent partition). The dependent variable was the amount of time that the female spent near a given male. The female was recorded as “preferring” a male when it spent more than half of the testing period near that male. The investigators compared this result against a control group (females who had not viewed a fight). The main result is that females “preferred” the loser. The authors conjectured that females might prefer to avoid the danger of injury and hence avoided the more aggressive winner. This study showed that female quail used reputation to learn the dominance of males.

Primates, too, have been the subject of social eavesdropping experiments (Abdai and Miklósi 2016; Anderson et al. 2017; Tennie et al. 2010). Russell et al. (2008) studied indirect reputation on four great ape species (chimpanzees, orangutans, gorillas, and bonobos). Here, apes were given the opportunity to observe playacted incidents between human actors. In every incident, one actor played the “beggar” who observed another human eating green grapes out of a transparent container and then extended his hand outward in front of the eater in a begging gesture. There were two types of incident: (1) a “nice” person gave grapes to the human who begged for it and (2) a “nasty” person ignored the begging gesture; then the beggar reached into the container to obtain a grape; then the

nasty person slapped him on the hand, preventing him from obtaining grapes. Subjects observed both nice and nasty incidents in every trial as uninvolved bystander. Next was the choice phase, where a barrier was lifted, allowing the subject into a different compartment where both nice and nasty actors were sitting side by side at adjacent windows. Each window had holes through which food could pass. The dependent variable was the amount of time (in seconds) that the subject spent near a given person (with neither person giving any food). The main result was that chimpanzees and bonobos together (but not other species) spent significantly more time near the “nice” window than the “nasty” window. Furthermore, over four trials, they collectively reduced the amount of time at the nasty window but did not reduce their time at the nice window. This study showed that *Pan* species used indirect reputation to gauge which of the two human actors were more likely to give food. A number of other studies subsequently used the same paradigm (reviews in Abdai and Miklósi 2016; Anderson et al. 2017; Tennie et al. 2010). One example was from Herrmann et al. (2013), who tested all four great ape species plus human children aged 2.5 years. They used the same basic design, but with a larger sample size, using a more diverse range of food for the animals, and, for children, they used toys instead of food. Their “direct” playacted incidents involved a “nice” person who attempted to give food to the apes or use toys to play with the children and a “nasty” person who tried to interrupt the food giving or play. The “indirect” incidents were the same except that the subject observed the incidents among third parties as an uninvolved bystander. The dependent variable was the subjects’ willingness to approach either the nice or nasty person. Overall, they found that orangutans and children preferred the nice person in both the direct and indirect situation. Chimpanzees also showed a preference for the nice person in the indirect reputation condition.

Anderson et al. (2013a) used a similar social eavesdropping paradigm on capuchin monkeys. Again, subjects were shown a playacted incident between two humans. In each trial, the monkey

observed either a “helpful” incident, or a “non-helpful” incident, and then was able to choose which of two people to approach for food. In the first part, every incident had an “attempter,” a person attempting to retrieve a toy from a transparent plastic container. The toy inside the container was clearly visible to all, and the subjects observed the attempter attempt to lift the lid from the container with no success. In each incident, there was another human sitting beside the attempter. The identity of the other person depended on the type of incident. In the “helpful” incident, the other person was the “helper.” After unsuccessfully trying to open the container, the attempter looked at the helper and held the container toward the helper. The helper then co-handled the container, and then the attempter was able to lift the lid and obtain the toy. In the “non-helper” incident, the attempter playacted the same thing: trying to remove the lid with no success and then looked at the helper and held the container toward the helper. Here, the non-helper turned away from the attempter and did not help. Subsequently, the attempter continued attempting to lift the lid with no success. In the second part of the trial, an opaque screen was lowered, blocking the previously observed area. Then the screen was lifted, revealing both helpful and non-helpful actors sitting side by side with a piece of food (monkey pellet) resting on the fingers of their open palms. The monkey had the choice to approach either the helpful or non-helpful person for food. Once the monkey had made its choice (by putting its hand through the 3-inch gap in front of the person’s hand), the selected person extended her hand to allow the monkey to take the food. Their main result was that the monkeys accepted food less frequently from the non-helpful person than the helpful person.

There are many other social eavesdropping studies beyond that mentioned above. Anderson et al. (2013b) did another study of capuchin monkeys, showing them incidents of humans in either a reciprocating (human A gives human B a set of balls and then B returns them) or a non-reciprocating condition (B does not return them). After giving the monkeys an opportunity to approach either the reciprocator or non-reciprocator for food, the monkeys chose the reciprocator. There has also been a burgeoning literature

on social eavesdropping in dogs (Abdai and Miklósi 2016; Anderson et al. 2017). One interesting study by Chijiwa et al. (2015) found that, when dogs were given a chance to observe their owners interacting with either a helper or non-helper for trying to retrieve an object from a container. When dogs were given an opportunity to approach the helper or non-helper, they approached the helper.

## Benefits and Evolution

Gossip and reputation are thought to have played an important role in our cognitive evolution and ability to thrive within cooperative groups (Dunbar 2004; Milinski 2016; Tennie et al. 2010). Reputation is beneficial in at least three ways: (1) benefit-to-approacher, (2) benefit-to-winner, or (3) benefit-to-group. The first benefit is that reputation provides opportunities for low-risk, low-cost, information gathering (McGregor 1993): in territorial birds, for example, eavesdropping helps animals to avoid injury by avoiding the winners of fights. The second benefit involves the winner (Adams 2001): when an animal has gained a reputation for winning fights, it saves that animal from needing to expend energy in further fights (because other animals will hesitate to attack). A third type of benefit relates to the “tragedy of the commons” (Hardin 1968; cf. Binmore 2007, pp. 27–29), whereupon a negative outcome (e.g., depletion of a resource) occurs because individuals are independently pursuing their own desires/needs without doing anything to avert the negative outcome. In various human-focused empirical and theoretical studies (see Milinski 2016), it has been shown that reputation actualizes better cooperative outcomes on a group level – based on the bottom-up explanation that individuals with good reputations tend to prosper and those with bad reputations do not.

Reputation can also be studied game-theoretically (e.g., Morris 1999). Game theory is a mathematical approach to investigating the costs and benefits of behavioral strategies, specifically focused on the dynamics arising from interactions between actors (Binmore 2007). Game theory is well-suited to analyzing conflicts/contests between animals (Adams 2001;

Maynard Smith and Harper 2003). One early game-theoretic study is the simulation study of Van Rhijn and Vodegel (1980), which quantitatively compared the success of various fighting strategies where a contestant (player) was facing an opponent whose fighting ability was either dominant, submissive, or unknown. The player had three options: make a threat display, engage in actual fight, or retreat. Their results showed that, out of four possible strategies, the most successful one was where the player starts off with caution, showing a threat display if the opponent was subordinate/unknown, never initiating with dominants (and retreating if encountering one), and then escalating into an actual physical fight if the opponent continued to appear subordinate/unknown. Key to success was that the player adopted a strategy contingent on updateable knowledge about the opponent's fighting ability.

On the topic of *indirect* reputation, one way to infer its adaptiveness in evolution is through mathematical modeling. Pollock and Dugatkin (1992) modeled the tit-for-tat (TFT) strategy: player 1 cooperates in the first encounter with player 2 and, if encountering player 2 again, copies player 2's previous action (cooperate if player 2 cooperated, defect if player 2 defected). Their aim was to compare the success of TFT to another strategy called "observer tit-for-tat" (OTFT), the same as TFT except that player 1 paid attention to player 2's previous behavior toward others (e.g., if player 2 defected on someone else, then OTFT would defect on player 2 even on a first encounter). Using the criterion of evolutionary stability (a strategy is successful if it can outcompete rival strategies in a survival-and-reproduction game), the result was that OTFT was more successful than TFT, but only in models that set a low probability of repeated encounter. The implication of their model was that indirect reputation is particularly adaptive in large, mixed, and dispersed populations.

## Definition

To define an action as *Rescue behavior*, Hollis and Nowbahari (2013; Nowbahari and Hollis 2010) proposed that four conditions should be met. Firstly, there is a victim endangered. The victim is in a situation that implies imminent direct physical harm and/or indirect harm through severe fitness decrease (e.g., releasing humans from a stressful situation that is harming dramatically their mental health and indirectly their fitness). Secondly, the behavior of the rescuer is suited to the circumstances of the victim's distress. This condition creates a connection between the rescuer's behavior and the victim's situation while, simultaneously, avoids referring to the rescuer's intentionality. This last element allows the inclusion of rescue behaviors actions performed by human and nonhuman animals. Thirdly, the rescuer places itself at risk by engaging in rescue behavior. This condition is linked to the classification of rescue behavior as an extreme case of altruism, which will be analyzed later. The fourth condition is that the act of rescuing is not inherently rewarding or beneficial to the rescuer. The only exceptions are the benefits associated with kin selection or reciprocal altruism, concepts that are explained later in this entry. This fourth

condition is difficult to evaluate in humans because rescue behavior could be inherently rewarding at a psychological level, for example, strengthening the perception of oneself as a good individual, which is less likely to occur in other animals.

The definition of rescue behavior does not require a successful rescue, nor necessarily implies prosocial motivation aimed to reduce other individuals' suffering. The existence of this motivation has been questioned in nonhuman animals. Therefore, the wide definition of rescue behavior includes acts performed by human and nonhuman animals (Hollis and Nowbahari 2013).

The third and fourth conditions of rescue behavior allow classification as an extreme case of altruism, a behavior that benefits another subject with a cost for the helper. The rescuers perform a behavior highly risky for themselves which is, nonetheless, not inherently rewarding for themselves (except for the cases explained by the two mentioned theories, kin selection and reciprocal altruism).

## Explanations of Rescue Behavior

Altruism implies a cost for the altruistic individual and, according to natural selection, it should be eliminated because it reduces the individual relative fitness (i.e., reproductive success in comparison with other subjects). This argument is especially problematic for an extreme case of altruism, such as rescue behavior, because the rescuer could die or be severely damaged by rescuing. Therefore, researchers ponder the ultimate causes of rescue behavior; that is, explanations of how this behavior has been selected through the species' evolutionary history. Those explanations address how rescue behavior contributes to the rescuer's gene propagation. Three theories have been proposed in this respect: kin selection, reciprocal altruism, and multilevel selection theory.

### Kin Selection

This theory was developed by Hamilton (1964), and as its name indicates, kin selection explains altruistic behavior toward genetically related subjects. Hamilton, studying the behavior of insects

like ants, bees, and wasps, proposed that altruistic behavior could imply an indirect fitness (i.e., the transmission of one's genes through other bodies). He synthesized this proposal in an equation: an altruistic behavior is more likely to be selected naturally when the relatedness degree between the altruistic individual and the recipient, weighted by the reproduction benefits for the recipient, is higher than the reproduction cost for the altruistic individual. If kin selection explains altruism toward a related individual, how to understand why this behavior is sometimes directed to a non-kin? Reciprocal altruism addresses this question.

### Reciprocal Altruism

This theory, proposed by Trivers (1971), explains that a subject might help unrelated recipients because they would return the help in the future, which increases the helper's survival probability and therefore, the natural selection of this altruistic trait. Reciprocal altruism is more probable when there are frequent interactions between a helper and the recipients, which can be found in these conditions: (1) low dispersal rate, then there would be more interactions between a subject and the same others, (2) interdependence of members, so they need to be closer to each other, and in consequence, there would be more interactions among them, and (3) long lifetime for helper and recipients, because then there are more opportunities for the interaction.

Whereas in kin selection theory, the selection operates at the genetic level, in reciprocal altruism theory the selection works at the individual level. A third selection mechanism, occurring at group level, is offered by the following model.

### Multilevel Selection Theory

This theory extends the selection from genes or individuals to a group level (Wilson and Sober 1994). According to within group selection, altruistic subjects would have a relative fitness disadvantage compared to selfish individuals, because altruists help selfish subjects, who receive help without returning it. However, according to between groups selection, those groups with a higher proportion of altruistic individuals would

have more chances of survival than groups with more selfish subjects. This is because the former groups are more prepared to defend themselves from external threats and maintain a feeding system than the latter ones. Hence, multilevel selection theory proposes that altruistic traits are selected at the group level when between groups selection prevails over within group selection.

### Rescue Behavior in Humans and Nonhuman Animals

In humans and nonhuman animals, rescue behavior has been addressed in field and laboratory studies. Rescue behaviors are rare, especially in nonhuman animals. However, there is evidence of rescue behavior in social species of ants, dolphins, birds, and primates (including humans).

In *Ants*, this behavior has been informed in field and laboratory studies with few ant species, as *Tetramorium* sp. *E* (Taylor et al. 2013), *Cataglyphis cursor* (Andras et al. 2020; Nowbahari et al. 2009, 2012), *Formica sanguinea* Latr., *F. fusca* L., and *F. cinerea* Mayr (Czechowski et al. 2002), *F. cinerea* (Miler 2016), and *Veromessor pergandei* (Kwapich and Hölldobler 2019). The evidence shows that ants only rescue homocolonial individuals. For example, in a laboratory study two American *Tetramorium* sp. *E* ants were chosen as the victim and potential rescuer in different trials. The victim was put in an antlion's (the predator) pit in such a way that it was stunned and with injured legs. The antlion captured the victim, and then the other ant (potential rescuer) was put in the sand. The rescue behavior was displayed in 36% of trials approximately, and the most common was pulling the victim's limbs (less sensitive ant area) and, in a few cases, the rescuer attacked the antlion or transported sand away from the victim's body. The risk for the rescuer was the possibility of being grabbed by the antlion, which actually happened in some trials (Taylor et al. 2013).

In *Nonhuman primates*, rescue behavior has been reported in white-faced capuchins (Jack et al. 2020; Perry et al. 2003; Vogel and Fuentes-Jiménez 2006), and chimpanzees (*Pan troglodytes*; Boesch 1991). Those field studies show rescue behaviors among conspecifics, but there is

no evidence about the extension toward other species. An example of rescue behavior was described in a field study in Costa Rica with white-faced capuchin monkeys (*Cebus capucinus*). In a behavioral observation, a female was rescued from a threatening situation. In the situation, monkeys were organized in two groups (Vogel and Fuentes-Jiménez 2006). Individuals from Group A left the resting area and were chased by subjects from Group B. Behind all of them, an adult female and her infant from Group A were in a pool. Males from Group B came back and surrounded her and her infant. Those males made threatening vocalizations toward the female and tried to grab her infant. The female made alarm calls and submerged herself and her infant into the water, only keeping both heads above. A male from Group A came back to the pool and made threatening vocalizations against males in Group B, who then left the female and her infant.

In *Dolphins*, there is also some evidence of rescue behavior among conspecifics, specifically in *Tursiops truncatus* dolphins (Siebenaler and Caldwell 1956). For example, in an American school of dolphins, one adult, partially stunned by a dynamite explosion detonated by a fishing boat, was helped by two other adult dolphins. The rescuers placed themselves below and on either side of the injured dolphin, and then carried the victim to the surface where it could breathe. The position of the rescuers implied risk for themselves: they were near the explosion source and could not breathe because they were submerged. After a moment, the rescuers moved away from the stunned dolphin and went to the surface and blew. Two dolphins (there is no clarity whether they were the same original rescuers) then appeared and displayed continuous help for the stunned dolphin. This conduct, detailed by Siebenaler and Caldwell (1956), shows a possible coordination in helping among dolphins.

In *Birds*, a field study presented the first evidence of rescue behavior in social birds: Seychelles warblers (*Acrocephalus sechellensis*) from Cousin Island (Hammers and Brouwer 2017). Those birds are most of the time foraging in the tree's canopy but when they are on the

ground, they can get entangled in the sticky seeds of the *Pisonia grandis* tree, the most common tree in the study area. In this situation, the Seychelles warblers' lives are at risk because they have problems to fly and the seeds are hard to remove. The victims made alarm calls and received help from conspecifics, which took off the seeds by pulling or picking them. Rescuers put their lives at risk because they can also get entangled in the seeds.

Finally, other studies in *nonhuman species* refer to rescue behaviors that would not meet the conditions proposed by Hollis and Nowbahari (2013). For example, there are reports of rodents or dogs rescuing other trapped rats or dogs in a tube, and people in a cubicle, but it is questionable if those individuals put themselves at risk (e.g., Carballo et al. 2020).

In *Humans*, there is evidence of rescue behavior displayed toward other human and nonhuman animals in different contexts, for example, wars, natural disasters, daily life, etc. This behavior has been performed by firemen, first responders, soldiers, and general population, among others (Atran 2010; Fredman et al. 2015; Thompson 2013; Whitehouse 2018). Most reports come from field studies, probably because putting a victim in danger in a laboratory would be against ethical standards in human research. Thus, most laboratory studies tend to evaluate willingness to perform rescue behavior but not the action itself. An example of rescue behavior was performed by owners of pets (cats and/or dogs) in Wisconsin, United States, when cars of a train carrying propane derailed, and caught fire (Heath et al. 2001). Officials from the Emergency Operations Center asked people living around this area to evacuate the place because there was a risk of a major explosion. Some people, whose pets were not evacuated in the first days after the derailment, illegally entered the dangerous zone, putting themselves at risk, and rescued their pets.

## Conclusion

This entry reviewed the ultimate causes of rescue behavior and the different types of this behavior

displayed by human and nonhuman animals. Rescuing a genetically related subject can be explained by kin selection, multilevel selection, or reciprocal altruism theories, while rescuing a non-related individual can be explained only by the latter theory. Specifically, when rescuing related individuals, rescuers would (a) propagate their own genes in the rescued animals (kin selection), (b) receive help in the future from the victim (reciprocal altruism), and/or (c) contribute to their group survival of genetically related members (multilevel selection). On the other hand, rescue behavior toward a non-kin can be explained by reciprocal altruism theory: rescuers would increase their survival likelihood by eventually receiving help from the rescued animal.

Evidence of rescue behavior is available for some social species. This social dimension has promoted interest in moral variables associated with rescue behavior, such as empathy, intentionality, and consciousness of other individuals' needs. Nevertheless, the evidence is not sufficient and unequivocal to conclude that those moral variables are present in nonhuman rescuers, mainly because an operational definition of such constructs is a complex task. The exploration of these and other related variables is one of the main challenges for animal cognition and behavior research agendas.

### Synonyms

Polygyny

### Definition

Resource defense polygyny is a mating system, whereby males of a species control a resource or territory necessary for successful female reproduction, and in which the male will mate with more than one female during a breeding season.

### Introduction

Resource defense polygyny is one of several different types of mating systems often observed in habitats with variation in the quality and distribution of resources. Different species will require different types of resources when determining habitat quality during the reproductive period. Factors that may increase the likelihood of polygynous behavior include the dependence by the animal on certain features in the habitat and time and resource requirements for male parental care (Emlen and Oring 1977). Polygyny often occurs in habitats with scarce resources. Females may have the capacity to assess resource quality within a male's territory and tolerate male polygynous behavior if her chance of reproduction within the high-resource quality territory is increased. The fitness benefits for the female under this system may be greater than if mating monogamously with a male who had secured poor resources.

When a female is selecting a mate, her decision is likely heavily based on two factors: the quality of the resources the male is defending and the quality of the male himself. If there is a cluster of resources that is appealing to a female, males of the species fight for control of those resources, thus indirectly controlling the female's ability to mate. In species that exhibit biparental care of offspring, the benefit of the male-defended resources and/or the genetic contribution of the male must outweigh the risk of extra-pair copulations or polygynous behavior where the male secures alternative mates (Emlen and Oring 1977). In polygynous relationships, males must balance perceived fitness tradeoffs in decisions to seek multiple mates. However, males that are polygynous typically exhibit greater fitness, provided costs of mate acquisition do not outweigh fitness gains. Males exhibiting polygynous behavior must also decide if the genetic benefit of mating with multiple females outweighs the fitness benefits associated with male parental care. For monogamy and parental care to be advantageous to a male, the cost of mating with multiple females must be greater than the cost of parental care. There are two groups of factors that impact fitness tradeoffs. First, there are factors that balance the costs/benefits of parental care in terms of survival rate of the offspring. Second, there are factors that impact the cost/benefit of multiple copulations (Westneat et al. 1990).

### Examples of Resource Defense Polygyny

An example of resource defense polygyny can be found in the yellow-bellied marmot (*Marmota flaviventris*), in which males guard caves that are valuable for shelter and hibernation. A group of females will co-occupy a specific cave with a male at a given time. Often these female groups are called harems and linked to harem defense polygyny; however, the male marmot is not forcing the female marmot into the cave. Instead, males are dominating the desirable cave resource, which is valuable enough that the females will tolerate male polygynous behavior.

Hummingbirds also exhibit resource defense polygyny associated with resources provided by their primary food source, nectar. Males will defend areas with substantial production of nectar flowers in a cluster. Female hummingbirds have substantial nectar requirements for effective parental care, and resource-defending males will allow select females access to the resource while excluding other individuals. In this example, the amount of resources (i.e., number of nectar producing flowers) the male controls will dictate the number of females he will secure as mates (Emlen and Oring 1977).

The Colombian cranainae (*Phareicranus pff. spinulatus*) is an Arthropoda species that also demonstrates resource defense polygyny. Males of this species use their long legs in direct conflict with other males to secure optimum habitat for female egg laying (García-Hernández and Machado 2018). Individuals either use a set of secondary legs to whip and momentarily immobilize other males, or use their first set of legs to strike the other secondary leg of competing males.

## Conclusion

Animals displaying resource defense polygyny have adapted to this mating system due to myriad factors including changes in male parental care, increasing variation or restriction of key resources in the environment, or other factors. Researchers suspect that resource defense polygyny can evolve to be an optimum strategy in resource or space-limited environments and will likely be evident in more species when studied extensively. The more likely that resources and parental care are the limiting factors, the more likely it is for a species to exhibit resource defense polygyny.

## Synonyms

Fighting Ability; Resource holding power

## Definition

Morphological and physiological traits affecting the ability to win a direct competitive contest over a limited resource.

## Summary

Animals use contests, with displays and/or fighting, as direct competition to resolve disputes over finite resources (Parker, 1974; Rudin and Briffa, 2012). The resources fought over can affect their fitness either directly (e.g., mating opportunities) or indirectly (e.g., food) (Palaoro and Briffa, 2017). The contests are frequently decided when one of the individuals withdraws from a fight or refuses to engage, and less frequently by one individual killing another. Morphological and physiological traits determining the potential to win these contests are defined as an individual's resource holding potential (RHP). The concept was initially proposed by Parker (1974) who referred to it as the 'resource holding power'. Traits typically considered to determine RHP include body mass, body size, weapons, contest experience, and physiological state (Batchelor et al., 2012; Hsu and Wolf, 2001; Parker, 1974). More recently some authors have suggested that also certain behavioral traits, such as daring or boldness, should be considered a RHP trait (Rudin and Briffa, 2012).

Physical RHP traits can be either offensive or defensive. Offensive traits include body size and strength, and defensive traits include stamina and the ability to endure damage and attacks (Palaoro and Briffa, 2017). These traits form the individual's fighting ability, which often determines the outcome of contests (Hsu and Wolf, 2001; Palaoro and Briffa, 2017). In social species the outcome also depends on the group size. Group RHP depends primarily on the number of group members and the RHPs of individuals within each group (Batchelor et al., 2012), although in some cases presence of an individual with very high RHP (e.g., a mature male) can offset any advantage in numbers (Cooper, 1991). The traits that determine RHP in contests can be a complex combination depending on the environment and resources being fought over.

Accurate assessment of RHP, both one's own (absolute RHP) and in comparison to their opponent's (relative RHP), is a key factor in determining the outcome of contests. Many intraspecific contest displays and initial fighting are ritualized in order to assess the opponent's RHP and reduce injuries (Keeley and Grant, 1993; Parker, 1974).

Prior visual assessment allows for assessment of size which can decrease contest duration, while initial fighting allows for assessment of strength and other traits (Keeley and Grant, 1993). If assessments of RHP are accurate it allows animals to avoid conflict, engage, or disengage from conflicts and therefore increase or limit the time and energy lost during contests as well as the potential for risk of injury (Arnott and Elwood, 2008; Parker, 1974). Variation occurs in individual's abilities to accurately assess RHP, and prior experience increase self-assessment of RHP, but does not necessarily affect fighting ability itself (Hsu and Wolf, 2001; Keeley and Grant, 1993). Many species have evolved behaviors or morphological traits that exaggerate the cues used for RHP assessment, such as displays of large teeth, horns, claws and other weapons, or ornamentation such as luxuriant hairs, feathers and fins. Such 'evolutionary cheating signals' are attempts to increase the apparent RHP, although such features are often good indications of an individual's fitness and absolute RHP (Parker, 1974).

Although RHP is a critical factor in determining the outcome of contests for a resource, empirical test have repeatedly demonstrated that individuals with higher RHP do not necessary always win a contest. Instead the outcome can also be influenced by other factors, including motivation (the subjective value individuals place on the resource), aggressiveness and ownership status (Allen et al., 2016; Arnott and Elwood, 2008; Batchelor et al., 2012; Parker, 1974). The initial owner of a resource is often more likely to win a contest, potentially due to either their experience or investment in the resource (Arnott and Elwood, 2008) or due to the benefits gained from the tenure of the resource itself (Parker, 1974). Rarity of a resource increases its value and therefore the motivation to obtain and investment in the resource, and also makes resource guarding more likely (Keeley and Grant, 1993; Parker, 1974).

Most studies to date have focused on intraspecific contests over resources. Although RHP in interspecific contests are understudied to date, they have the potential for increasing our understanding of RHP with future study. The ability to

assess RHP varies by species (Arnott and Elwood, 2008), as does size, strength, and other morphological traits that determine RHP. As with intraspecific contests, size and stamina are likely critical to RHP and determining the winner of interspecific contests. Initial research shows that species-specific weapons are also important in these contests (Allen et al., 2016; Martin and Ghalambor, 2014), as well as social behavior since group-living species are clearly advantaged as greater numbers can outweigh body-size differences (Cooper, 1991). Species-specific traits create advantages and mismatches in RHP (Allen et al., 2016; Martin and Ghalambor, 2014), that make assessment important. Most interspecific bouts are over food and other resources, indirect sources of fitness that can hold less value than direct sources of fitness. However, interspecific contests also more often result in death of one or both of the contestants than in intraspecific contests, thus directly affecting fitness.

## Synonyms

Breathing; Lung

## Definition

System that allows animals to breathe and exchange oxygen and carbon dioxide throughout the body; it is composed of nose, pharynx, larynx, tracheobronchial tree, and lungs.

## Introduction

The respiratory system can be divided into the upper respiratory system, which is composed of the nose and pharynx, and the lower respiratory system which is generally composed of the larynx, tracheobronchial tree, and the lungs. This vital system of the body has many functions including olfaction detection, vocalization production, behavioral cues, filtration and humidification of inhaled breaths, and of course gas exchange. This text will discuss the anatomy and function of the respiratory system as well as domestic animal differences that may be important in a clinical setting.

## Upper Respiratory System

The upper respiratory system is composed of the nose and pharynx (Tortora and Derrickson 2009).

### Nose

The nose allows entrance of an inhaled breath to be carried towards the lungs or the olfactory center, warms and humidifies incoming air, and contributes to animal behavior. For example, a horse exhibits “flared nostrils” when angry. The form of the nares is altered by raising the ala via facial musculature or by breathing deeply/sniffing. The nose consists of the external nose, the nares, paired nasal cavities, and the paranasal sinuses. Unlike humans, animals’ noses are generally contoured within the muzzle. In most domestic animals, the external nose is composed of cartilaginous material covered by thick keratinized epithelium. The left and right nasal cavities are separated by a nasal septum cranially which is mostly cartilaginous but is ossified caudally.

The hard palate forms the floor of the nasal cavities separating them from the oral cavity. Nasolacrimal ducts and serous lateral nasal glands empty into the nose which aids in humidification of the air. The right and left nasal cavities join caudally and are filled with nasal conchae (usually dorsal, middle, and ventral conchae). The nasal conchae are composed of tissue with extensive vasculature whose purpose is to warm the incoming air. The conchae mucosa thickness depends on the health of the vasculature. For example, if the vessels are swollen from inflammation/congestion, this leads to decreased airflow and decreased sense of smell which is often associated with the common cold in humans. These conchae are separated by ethmoidal meatuses. The dorsal meatus carries inhaled air to the olfactory mucosa. The middle meatus allows the sinuses to drain. The ventral and common meatuses carry air to the pharynx on its way to the lungs (Dyce et al. 2002).

### Pharynx

The pharynx is a passageway for air and food. It serves as a resonating chamber for vocalization and also contains the tonsils. It is divided into three portions – the nasopharynx, the oropharynx, and the laryngopharynx. The soft palate separates the nasopharynx (which lies dorsal to the soft palate) and the oropharynx (which lies ventral to the soft palate).

The nasopharynx is lined by pseudostratified ciliated columnar epithelium which works to move debris collected from the incoming air towards the laryngopharynx where it can be swallowed into the esophagus. The nasopharynx also communicates with the middle ear to equalize air pressure during changing altitudes. The oropharynx is a passageway for food or air entering through the mouth and is lined by nonkeratinized stratified squamous epithelium which is able to better sustain damage from abrasive food particles compared to the pseudostratified ciliated columnar epithelium of the nasopharynx. The palatine tonsils are located in the oropharynx. The laryngopharynx lies caudal to the nasopharynx and oropharynx. It enters directly into the esophagus and larynx. The larynx, or “voicebox,”

then leads into the trachea (Tortora and Derrickson 2009).

## Lower Respiratory System

The lower respiratory system includes the larynx, tracheobronchial tree, and lungs (Tortora and Derrickson 2009).

### Larynx

Commonly known as the voice box, the larynx connects the laryngopharynx to the trachea. The function of the larynx is to prevent aspiration of food/liquids, produce sound, and capture dust that escaped the upper airways (Tortora and Derrickson 2009). The larynx is composed of cartilages which vary from species to species. The major laryngeal cartilages present in most species include the epiglottis, thyroid cartilage, cricoid cartilage, and the paired arytenoid cartilages. When at rest, the epiglottis allows air into the trachea. When swallowing, the epiglottis covers the entrance to the larynx directing food into the esophagus and preventing food from entering the trachea. The thyroid cartilage is the largest of these cartilages and forms the majority of the laryngeal floor. The most rostral part is thickened and corresponds with the “Adam’s apple” in humans (Dyce et al. 2002). The cricoid cartilage usually has the appearance of a “signet ring” which articulates rostrally with the thyroid cartilage and dorsally with the arytenoid cartilages (Dyce et al. 2002). The arytenoid cartilages are mobile and influence changes in position and tension of the vocal folds (Tortora and Derrickson 2009). The arytenoid cartilages and the vocals folds are collectively referred to as the glottis. The vocal folds of the glottis are appropriately named as they produce sound as air flows over them. The pitch is controlled by thickness, length, and tension of the folds, and the sound is altered in the resonating chamber of the pharynx (Dyce et al. 2002). The lining of the larynx rostral to the vocal folds is composed of nonkeratinized stratified squamous epithelium. Caudal to the vocal folds, the lining is composed of pseudostratified ciliated columnar epithelium that moves up towards the

pharynx to prevent debris from entering the trachea and traveling into the lungs. This epithelium contains goblet cells that produce sticky mucus to trap dust which can then be transported up the mucociliary elevator (Tortora and Derrickson 2009). In addition to preventing aspiration of food/liquids, phonating, and capturing debris, the larynx also plays a role in strenuous breathing and coughing. During vigorous breathing, the arytenoids are actively abducted to allow for larger breathes to be taken. During coughing, large expiratory forces build up against the closed glottis and allow for a forceful expulsion of air when opened. The glottis will also close with increased thoracic pressure/straining such as during defecation, forceful micturition, and parturition (Dyce et al. 2002).

### Tracheobronchial Tree

The trachea is a tubular passageway composed of cartilage which may form complete or incomplete rings, depending on the species (Dyce et al. 2002). Animals with complete tracheal rings are usually more difficult to intubate for procedures. Incomplete tracheal rings are connected by the trachealis muscle which allows the diameter of the trachea to change. The trachea is lined by pseudostratified ciliated columnar epithelium which functions similar to the ciliated epithelium of the larynx (Tortora and Derrickson 2009). In most animals, the trachea travels from the larynx, through the thoracic inlet, and bifurcates into bronchi. However, in ruminants and pigs, another bronchus arises proximal to the tracheal bifurcation to supply the cranial lobe of the right lung (Dyce et al. 2002). The right bronchus is slightly shorter than the left, making aspiration into the right lung more common than into the left. The primary bronchi (main bronchi) continue down into the lungs and become the secondary bronchi, tertiary bronchi, bronchioles, and terminal bronchioles. The secondary bronchi are also referred to as lobar bronchi as there is one for each lung lobe. Tertiary bronchi (segmental bronchi) mark the transition from pseudostratified ciliated columnar epithelium to ciliated simple columnar epithelium in the bronchioles. The larger bronchioles contain goblet cells, but the smaller bronchioles do not.

In the terminal bronchioles, the epithelium transitions to simple non-ciliated cuboidal epithelium with debris being removed by macrophages rather than carried orally by the mucociliary elevator. The tracheobronchial cartilage structure continues to the level of the bronchioles, with gradual replacement of cartilage by smooth muscle. The terminal bronchioles are only supported by smooth muscle which can be a problem during asthma attacks. During an asthma attack, the smooth muscle in the terminal bronchioles constricts, closing off the airways (Tortora and Derrickson 2009).

## Lungs

The main function of the lungs is to facilitate gas exchange. The lungs are free-floating structures within the thorax suspended from the mediastinum. They change in size depending on respiration, although the right lung is always larger than the left due to the natural position of the heart. The left and right lungs are subdivided into different lobes which vary depending on the species. Most animals have an accessory lung lobe that is associated with the right lung and lies over the caudal vena cava (Dyce et al. 2002). The apex of the lungs lies cranially with the base of the lungs contacting the diaphragm caudally. The costal surface lies against the ribs and the mediastinal surface lies against the mediastinum. The lungs are covered by a pleural membrane which is composed of the parietal pleura and the visceral pleura. The parietal pleura lines the wall of the thoracic cavity and the visceral pleura lies over the lungs. Between the pleurae, there is a pleural cavity that contains fluid that allows the lungs to easily slide against the pleura during expansion upon inhalation (Tortora and Derrickson 2009). The inner portion of the lungs includes the tracheobronchial tree as discussed above. The terminal bronchioles give way to alveolar ducts, alveolar sacs, and alveoli as continued branching occurs (Dyce et al. 2002). Alveolar sacs consist of two or more alveoli that share a common alveolar duct opening (Tortora and Derrickson 2009). Gas exchange takes place within alveoli. Alveoli are small spaces that consist of thin epithelium closely opposed to pulmonary capillaries (Dyce

et al. 2002). Gas exchange occurs by diffusion, with oxygen diffusing into the capillaries and waste gases such as carbon dioxide diffusing from the capillaries into the alveolus. Inhalation is an active process involving contraction of the diaphragm and external intercostal muscles. The lungs are pulled down and expanded allowing for air intake. Exhalation is normally a passive process that results from elastic recoil of the chest wall. However, during strenuous exercise or disease, exhalation can become an active process with forceful contraction of the abdominal muscles and internal intercostal muscles (Tortora and Derrickson 2009).

## Domestic Animal Differences

### Dogs and Cats

Dogs' skull conformation widely varies compared to cats'. Dogs may be referred to as dolichocephalic, mesaticephalic, or brachycephalic. These dogs have long, medium, or short noses respectively. In many brachycephalic dogs, the nasal conchae are contained in such a small space that it causes breathing through the nose almost impossible. These dogs also usually have a soft palate that is disproportionately long and lies over the entrance to the larynx, causing respiratory difficulties. Dogs' ethmoidal conchae, which allow for sense of smell, are actually larger and more extensive than their nasal conchae. Cats have a unique adaptation to their larynx which allows them to purr. Purring is produced by fast twitching of the muscles in the larynx and diaphragm. The laryngeal muscles cause the glottis to rapidly widen and narrow leading to the vibration of air which we know as purring. Dogs and cats have incomplete tracheal rings. Both have the same lung lobe anatomy – the right lung being divided into the cranial, middle, caudal, and accessory lung lobes, and the left lung being composed of a divided cranial lung lobe and a single caudal lung lobe (Dyce et al. 2002).

### Horses

The nostrils of horses are especially large and are supported by alar cartilages which allow them to

actively flare the nostrils during certain behaviors. The alar cartilages are also important because horses are obligate nasal breathers. During strenuous exercise, the horse is able to actively widen the nostril to allow for a bigger breath. Within the nose, there is a blind nasal diverticulum dorsal to the actual nasal cavity. When passing a nasogastric tube, it is important to pass the tube central and ventral to avoid the nasal diverticulum. The nasopharynx contains flaps that overlie the entrance to the auditory tubes. These flaps open during swallowing, so the horse is only able to equalize pressure during swallowing. Horses have incomplete tracheal rings. The lungs are more equal in size than in any other species and are elongate. Because of this, the left and right lungs are both only divided into cranial and caudal lung lobes, with the right lung also having the accessory lung lobe (Dyce et al. 2002).

### Ruminants

The oropharynx in ruminants is particularly small, restricting the size of food boluses that these animals can ingest. During eructation, the pharynx directs most of the eructated gas into the lungs. The reason for this is unknown, but animals on certain rations may have lung pathology associated with this phenomenon. Ruminant intubation may be limited by the small size of the glottis cleft and the slight caudal deflection of the entrance to the larynx. Ruminants have incomplete tracheal rings and a bronchus arises proximal to the tracheal bifurcation to supply the cranial lobe of the right lung. The right lung is composed of cranial, caudal, middle, and accessory lung lobes. The left lung is composed of divided cranial lobes and a single caudal lobe. As other animals, the diaphragm predominates normal breathing activity for ruminants. However, cattle have been known to survive diaphragmatic paralysis. Unlike horses, which have a large reserve capacity, ruminants have a small total alveolar surface area, of which a large portion is required for basal needs. Therefore, during stressful circumstances, there is not much more gas exchange area that can be utilized (Dyce et al. 2002).

### Pigs

Unlike noses of other animals, pigs have a snout that has a rounded moveable tip that incorporates the upper lip. Pigs use their snouts for rooting behavior. Some farmers prevent rooting behavior by placing rings through the dorsal border of the snout rather than the nostrils as seen in bulls. Pigs have a very good sense of smell which the French exploit by having pigs search for truffle mushrooms. Pigs have a unique feature within the pharynx called the pharyngeal diverticulum, which arises from the pharyngeal wall dorsal to the entrance to the esophagus. This structure is important to locate and avoid when dosing pigs with syringes, because injections into the pharyngeal diverticulum can cause serious injury to underlying tissues. The larynx has lateral ventricles and forms an obtuse angle with the trachea, both of which cause intubation to be difficult. Pigs have incomplete tracheal rings. The right lung is composed of cranial, middle, caudal, and accessory lobes. The left lung has a divided cranial lobe and a caudal lobe. Like in ruminants, the cranial lobe of the right lung is ventilated by a separate tracheal bronchus that arises before the tracheal bifurcation (Dyce et al. 2002).

### Ferrets

Ferrets are obligate nasal breathers. The trachea has incomplete rings and is 2–3 times the length compared to dogs and cats. The left lung is divided into cranial and caudal lobes while the right lung is divided into cranial, middle, caudal, and accessory lobes. Ferrets have extremely large lung capacities, having the second largest lung capacity of all mammals behind the sea otter. Their large lung capacity allows for successful underground hunting. Ferrets also have very compliant chest walls, which allow them to turn in tight spaces. Like humans, ferrets vasoconstrict pulmonary vessels under hypoxic conditions such as changes in atmospheric pressure (Johnson-Delaney and Orosz 2011a).

### Guinea Pigs and Chinchillas

Guinea pigs and chinchillas are obligate nasal breathers. Guinea pigs have small vocal folds compared to other animals but are still able to

vocalize loudly. For both guinea pigs and chinchillas, the right lung is divided into cranial, caudal, and accessory lobes, and the left lung is divided into cranial, middle, caudal, and accessory lobes. Compared to other animals, guinea pigs and chinchillas have small lungs because the heart occupies most of the thoracic cavity. It is interesting to note that on radiographs, bony spicules may appear in the lungs of guinea pigs which are a normal radiographic finding. These spicules are often asymmetric throughout the lungs and may be mistaken for foreign bodies (Yarto-Jaramillo 2011).

### Hedgehogs and Sugar Gliders

Hedgehogs rely heavily on sense of smell to navigate, detect predators, and communicate. An interesting behavior that hedgehogs possess is known as “self-anointing” which occurs during an intense olfactory stimulation such as anesthetic gases, perfumes, cat food, etc. The hedgehog will hypersalivate and slather the saliva over its spines on its flank and back with its tongue. This behavior is thought to be used to mark the individual or the surrounding territory. Hedgehogs usually have a silent respiration; however, when frightened, they may exhale forcefully. This hissing sound should not be confused with respiratory distress. Another important fact is that hedgehogs undergo hibernation when the temperature drops to a certain degree or estivation when the temperature rises to a certain degree. The degree at which this occurs depends on the breed of hedgehog. Captive hedgehogs do not undergo hibernation unless there is a temperature discrepancy or a nutritional issue. Normal respiratory rate during hibernation may drop to 1–8 breathes per minute. Hibernation actually increases the blood oxygen affinity and blood-to-tissue diffusion of oxygen so this lower respiratory rate still adequately supplies the entire body with oxygen. Sugar gliders also rely on sense of smell for communication via multiple scent glands and make a variety of odd vocalizations that should not be confused with respiratory disease. While sugar gliders do not undergo hibernation, they may exhibit torpor (a shortened hibernation that lasts anywhere from 2 to 23 h) and huddling behavior. Oxygen

consumption is decreased at this time. Torpor is triggered by starvation or lack of foraging rather than temperature changes, so if a client presents a sugar glider with this issue, husbandry and nutrition are the key issues to focus on (Johnson 2011).

### Mice, Rats, Hamsters, and Gerbils

All rodents are obligate nasal breathers. Mice, rats, and guinea pigs have high chest wall compliances. Mice, rats, hamsters, and gerbils have incomplete tracheal rings. Rats possess a special nasal gland called the Steno’s gland that is located in the rostral maxillary sinus and produces watery secretions to humidify inspired air and regulate mucus viscosity. Newborn rats have no alveoli or alveolar ducts, and gas exchange occurs in sacculi until about 4 days of age. By day 7, the rat lung is mature. Rat lungs do not contain bronchioles. Rats also have unique serous cells within their respiratory epithelium that secrete serous material to decrease viscosity in the airways. The rat’s lung surfactant is high in polyunsaturated phospholipids rather than monounsaturated phospholipids compared to other mammals. Like rats, hamsters also possess a Steno gland along with 13 other nasal serous glands and do not have bronchioles. In mice, rats, hamsters, and gerbils, the left lung is composed of a single lobe. In mice, rats, and gerbils, the right lung is divided into cranial, middle, caudal, and accessory lung lobes. The hamster has an extra right lung lobe known as the intermediate lung lobe (King 2011).

### Rabbits

Rabbits are obligate nasal breathers with incomplete tracheal rings. They have sensory pads on their nostrils which makes the nose a sensitive area. When breathing normally, the nose is still, but rabbits’ noses may twitch up to 150 times per minute. Both the left and right lungs have cranial, middle, and caudal lobes, with the right lung also possessing an accessory lobe. The diaphragm is the sole muscle responsible for inhalation (Johnson-Delaney and Orosz 2011b).

### Chelonians (Turtles, Tortoises)

Chelonians have significant differences in their respiratory system. Their trachea is short

and flexible which allows for retraction of the head into the shell and is composed of complete tracheal rings. Chelonians do not have a tracheo-bronchial tree, but it instead possess unbranched interpulmonary bronchi with ediculi and faveoli as the gas exchange sites rather than alveoli. Their lungs have limited room to expand due to their bony shell. They also do not have a diaphragm. Ventilation is achieved by contraction and relaxation of the inguinal, axial, and shoulder muscles, so it is normal for the limbs to move slightly during respiration. Unlike other animals that rely on negative pressure ventilation to breathe, chelonians rely on positive pressure ventilation which allows them to ventilate normally even with a compromised shell. In general, open mouth breathing in these animals is a sign of respiratory distress. However, they may exhibit movement of the ventral mandibular area called “gular pumping” which may be mistaken for open mouth breathing. Gular pumping in chelonians is a behavior used to assist in olfaction contrary to gular pumping in amphibians which is part of normal respiration (Bennett 2011).

### Birds

Like chelonians, birds have major differences in their respiratory system compared to domestic mammals. The nostrils of birds are located at the base of the beak. In some species of birds such as psittacines, pigeons, and raptors, the nostrils are covered by a cere which is a membrane that may be a different color depending on the sex of the bird. For example, male budgerigars have a blue cere and females have a light brown cere. The nostrils lead into a divided nasal cavity that, through the choana, communicate with the oropharynx. Birds have a nasal gland within the nasal cavity similar to the Steno gland in rats and hamsters. The larynx of birds does not contain vocal folds. Instead, vocalization is produced by the syrinx, a specialized structure that lies at the tracheal bifurcation. In male ducks and swans, an osseous bulla is present on the left side of the syrinx, believed to be a resonator. Song birds have complex syringeal muscles that allow for a variety of sounds to be produced. The trachea in birds is composed of

complete tracheal rings and, in long-necked birds, can be so extensive that it folds back on itself. The true lungs in birds are small and lie craniodorsally to the heart, but do not contact the heart. The lungs have an extensive cartilage make-up and are non-expansile. Birds do not have a diaphragm, and instead rely on rib cage movements to breathe. At the tracheal bifurcation, primary bronchi give way to secondary bronchi which communicate with air sacs. Air sacs are actually enlargements of the bronchial system that have diverticula that extend to enter various bones and skeletal muscles. The secondary bronchi give off 400–500 parabronchi in the lungs where counter-current gas exchange takes place. The complete respiratory cycle of the bird requires two breath cycles. On the first inhalation, air is moved into the caudal air sacs. On the first exhalation, air is moved into lungs. The second inhalation moves air into the cranial air sacs. The second exhalation moves the air out of the bird. Inspiration draws air through the lungs and into the air sacs – the caudal air sacs receive fresh air and the cranial air sacs receive relatively de-oxygenated air. During expiration, the air sacs are compressed and air from the caudal air sacs flows through the lungs and air from the cranial air sacs is expelled. In this way, the bird respiratory system is extremely efficient as there is always oxygen-rich air moving through the lungs, which is especially important during flight when the bird is using massive amount of oxygen at high altitudes (Dyce et al. 2002).

### Conclusion

While there are many species variations in the anatomy of the respiratory system, the function remains cohesive across all species. The respiratory system enables animals to smell, vocalize, communicate, filtrate, and humidify incoming air and exchange gas to provide the body with oxygen and rid the body of waste gases. A compromised respiratory system may be life-threatening to any animal. However, understanding normal respiratory behaviors in some animals may be necessary to differentiate behavior from disease.

Restraint is a condition of being inhibited or controlled (Merriam-Webster Dictionary online 2019). Restraint can be physical, chemical, and psychological (Sheldon et al. 2006; Browning 2012; Lawson 2004). In reference to animals, it is necessary to use restraint in order to perform medical procedures, give medications, to collect samples for diagnostic tests and to complete husbandry needs. In some cases animals serve a valuable use and some form of restraint is necessary for them to complete the task. Over the past three decades, there has been a definitive shift from acting from the standpoint of completing tasks as quickly as possible despite the struggle or stress from the animal to spending time calming and reducing the stress placed upon the animal in order to complete the task. Studies have found that each time an animal is stressed during handling it not only can impact the animal's health but also adversely affect future handling (Hammerle et al. 2015).

## Physical Restraint Can Be Manual or Mechanical

Manual restraint is the forced restriction of movement of all or part of an animal's body by an individual. There is a large variety of manual restraint techniques that those in the professions of research, veterinary medicine, and farming are trained extensively in to stay safe and keep the animal safe. How the animal is held depends on the species, the ethology of the animal, and how

that species can cause damage to the handler(s). Specifically, the animal's most dangerous body part is controlled first, and then through the use of pressure points, the animal is kept from moving. For example, the head of a dog would be the primary body part to keep from moving, as the teeth and mouth are the most dangerous.

Mechanical restraint is using a device to immobilize the animal. There are many restraint devices but some of the more common are: leashes, slip leads, muzzles, stanchions, squeeze chutes, cat bags, towel wraps, head collars, hip clamps, head halters, body harnesses, fences, invisible fences, cattle prods, hog snares, bridles, rabbit boxes, and face masks. Physical restraint has evolved over the last two decades from forceful immobilization to using mechanical devices to calm animals while also immobilizing them. These accommodations both keep staff members safe as well as calm the animal (Rudolph 2015).

Chemical restraint is the use of compounds to either sedate or anesthetize an animal to a point of immobility or compliance. Chemical restraint is used when physical restraint is not possible or the animal's stress or physiological state would make it dangerous to physically restrain. Over the past two decades chemical restraint is being used more often as a means of causing less stress to animals along with being more efficient (Hammerle et al. 2015). There is inherent risk using chemical restraint, especially if the animal's health status is not well known. However, in the professional animal fields, it is found that the risk of chemical restraint is preferable to the risk of the animal becoming overly stressed and the subsequent physiological and psychological consequences due to the excessive stress, (Hammerle et al. 2015). Recommended medications to relieve stress and at times immobilize patients in veterinary clinics are: BZD's (benzodiazepines), TCA's (tricyclic antidepressants), SARI's, (selective serotonin reuptake inhibitors), SARI's (dual serotonin 2A agonist/serotonin reuptake inhibitors), MAOI's (monamine oxidase inhibitors), Buspirones, centrally acting 2A agonists, and local anesthetics (Hammerle et al. 2015). The use of these anxiolytics are to relieve fear, anxiety, and stress (FAS), in the animal along with low stress handling to make medical exams and procedures more efficient and smooth.

Psychological restraint is the use of an animal's ethology, body language, and learning theory to gain compliancy (Browning 2012). Learning theory is the combination of classical conditioning and operant conditioning. Classical conditioning is the associations made between an external stimuli and internal physiological response. Operant conditioning is associations made between an act or nonaction on the environment and the subsequent consequence. Within operant conditioning, there are four possible consequences: positive reinforcement, positive punishment, negative reinforcement, and negative punishment (Pryor 1999). Positive reinforcement is when the consequence is added (positive) to increase the probability of the preceding behavior to be repeated (reinforcement). Positive punishment is when the consequence is added (positive) to decrease the probability of the preceding behavior to be repeated (punishment). Negative reinforcement is when the consequence is removed (negative) to increase the probability of the preceding behavior to be repeated (reinforcement), where negative punishment is the consequence removed (negative), to decrease the probability of the preceding behavior being repeated (punishment). The four possible outcomes of an individual's actions are what are known as the learning theory quadrant (Pryor 1999).

Psychological restraint is becoming a focal point of animal restraint over the last 30 years (Browning 2012; Wyatt 2013; Reiche 2016; Moffett 2015). Historically, the use of negative reinforcement has been the primary psychological restraint used along with manual and mechanical physical restraint. For example, when working with horses, a person will apply pressure on to the horse through a physical restraint until the animal complies slightly at which point the pressure is taken away; thus the animal "learns" that by not fighting the pressure is removed. There has been a strong history of positive punishment used in past decades when it came to controlling an animal that has dropped in popularity in the animal professions. Devices such as cattle prods and whips are now considered last resort measures in most professions as a means of controlling animals (Hammerle et al. 2015). Studies have shown that the use of cattle prods used in the beef industry is at 5.5%, which is well below the 10%

accepted limit placed by the Beef Quality Assurance, BQA (Woiwode and Grandin 2014).

A pioneer in psychological restraint is Dr. Temple Grandin, a professor from Colorado State University, with her use of chute and squeeze chute designs for large moving large animals. Through strategically placed curves and blind spots, she has improved the efficiency of the meat industry as well as decreased stress and anxiety for animals (Grandin 1995). By viewing a facility with an animal's ethology in mind, Grandin has succeeded in making the environment less threatening and thus reducing the stress and sympathetic nervous system response of the animal, making the whole system more efficient. Her work was groundbreaking in the field of farming and agriculture. Several facilities have taken to implementing Dr. Grandin's chute designs and auditing system to make production more efficient (North American Meat Institute 2017).

Another pioneer in psychological restraint is Dr. Sophia Yin, a veterinarian and animal behaviorist. Dr. Yin began a movement of stress free handling and restraint in the field of veterinary medicine. Dr. Yin developed a series of books, videos, and workshops on the use of negative reinforcement and positive reinforcement as a means of desensitizing and counter condition animals to medical restraint and procedures. Her work has been eye opening in the field of veterinary medicine.

Dr. Marty Becker, a veterinarian and popular radio personality, recently developed a certification program for veterinary professionals in the art of fear-free veterinary visits. Through the fear-free certification process, veterinary and animal professionals are taught to work with companion animals in as fear free manner as possible. First, the individual is taught the normal ethology of the animal, deciphering their body language, and understanding the basics of learning theory, an individual is taught how to approach and measure an animal's FAS: Fear, Anxiety, and Stress. If an animal's FAS is measured as high chemical restraint is used early on so as to not worsen the animal's FAS for future visits (Browning 2012).

Many research facilities are training animals to take an active role in their husbandry and medical procedures. Ken Ramirez, the head curator and

trainer at the Shedd Aquarium in Chicago, Illinois, is a forerunner in educating professionals in how to train exotic and wildlife species in cooperating in their own husbandry and medical care (Ramirez 1999).

An example of active compliancy is primates, being trained to place their limb outside their cage and hold it there until the caregiver has taken a blood sample. The animal is then rewarded with a treat of some kind (positive reinforcement). This use of positive reinforcement has been implemented across species of wildlife and domestic species in research and conservation facilities such as zoos and aquariums (Grandin 1997; Phillips et al. 1998). This means of acquiring active compliance is becoming more common place in the veterinary field as well.

Restraint is an integral part of managing and caring for animals. What used to be a means of obtaining control via force and coercion has begun to shift toward a more cooperative endeavor.

Molecular scissors; Restriction endonucleases

## Definition

A restriction enzyme is a site-specific endonuclease encoded by bacteria and archaea that recognizes a specific, short nucleotide sequence and cuts the DNA only at that specific site, i.e., restriction site.

It provides a defense mechanism to bacterial host against invading viruses, i.e., bacteriophages (Arber and Linn 1969; Krüger and Bickle 1983). Basically, restriction enzymes were named for their ability to restrict the growth of bacteriophages in a host bacterial cell by selective cleavage of the invading foreign DNA. This process is called restriction digestion. Interestingly, the host DNA is protected from their own restriction enzymes by the activity of

a modification enzyme (methyltransferase or methylase), which detects the same restriction site as the restriction enzyme and methylates a specific nucleotide (e.g., 4-methylcytosine, 5-methylcytosine, 5-hydroxymethylcytosine, or 6-methyladenine) on each strand within this restriction site. Methylation of only one strand, i.e., hemi-methylated state of restriction site, is also protected from restriction enzyme. Together, these two processes constitute the restriction modification (RM) system.

## Restriction Site

Each restriction enzyme identifies a specific sequence of nucleotides (between four and eight bases) and makes cut in both strands of the double-stranded DNA (Kessler and Manta 1990). Many of the restriction sites are palindromic in nature, i.e., reads same forward and backward. These palindromes could be mirrorlike (viz., GTAATG) or inverted repeat (viz., GGATCC being complimentary to CCTAGG). Inverted repeat palindromes are more common with greater biological importance than mirrorlike palindromes.

Once restriction enzyme recognizes restriction site, it can generate either sticky ends (e.g., *EcoRI*, *BamHI*, *HindIII*, etc.) or blunt ends (e.g., *SmaI*, *EcoRV*, etc.) depending upon type of restriction enzyme (Fig. 1).

Different restriction enzymes that recognize the same restriction sequences but cleave at different location are called neoschizomers (e.g., *ApaI* and *Bsp120I* are neoschizomer pair). On

the other hand, when recognize and cut in the same site or location they are called isoschizomers (*SmaI* and *XmaI* are isoschizomer pair).

## Types of Restriction Enzymes

Based on enzyme subunit composition, cofactor requirements, nature of their target sequence, and position of restriction site relative to the target sequence, restriction enzymes are of four types (Types I, II, III, and IV):

1. *Type I restriction enzyme* – It cuts at sites far from a recognition site (asymmetrical in nature) and requires both ATP and S-adenosyl-L-methionine (AdoMet) as cofactor to function. It has a feature of both restriction digestion and methylase.
2. *Type II restriction enzymes* – It cleaves within or at short-specific distances from a recognition site (palindromic in nature) and mostly requires magnesium to function. It has only feature of restriction digestion independent of methylase.
3. *Type III restriction enzymes* – It recognizes two separate non-palindromic and inversely oriented sequences and cleaves at 20–30 base pairs away from a recognition site. It contains more than one subunit and requires ATP for restriction digestion and S-adenosyl-L-methionine for DNA methylation.
4. *Type IV restriction enzymes* – It recognizes modified DNA (methylated, hydroxymethylated, and glucosyl-hydroxymethylated). Examples are McrBC and Mrr systems of *E. coli* (Table 1).

| Cofactors and activators | Mg <sup>2+</sup> , AdoMet, ATP (hydrolyzed)       | Mg <sup>2+</sup>                                               | Mg <sup>2+</sup> , AdoMet (stimulates activity but not required), ATP (not hydrolyzed) | Mg <sup>2+</sup> , AdoMet                                                    |
| Recognition site         | Interrupted bipartite                             | Palindromic or interrupted palindrome                          | Non-palindromic                                                                        | Interrupted bipartite                                                        |
| Cleavage site            | Cleave far from recognition site                  | Defined, within restriction site, give sticky or blunt ends    | Cleaves ~25 bases away from restriction site                                           | Cuts both strands on both sides of restriction sites and leaves 3' overhangs |
| Subunits and structure   | Pentameric complex (2R, 2M and 1S)                | Homodimer (2R-S)                                               | Both R and M-S required                                                                | Heterotrimer (2 R-M, 1S)                                                     |
| Methylase features       | Heterodimer (1M, 1S) or heterotrimer (2M, 1S)     | Separate, single, monomeric (M-S)                              | Methylates adenines, only one strand independently                                     | Same heterotrimer (2 R-M, 1S)                                                |

More than 3000 restriction enzymes have been studied in detail till now, and more than 600 of them are available commercially (Roberts et al. 2007). These enzymes are key tools in molecular cloning.

## Application of Restriction Enzymes

### (A) Gene cloning and protein expression

Restriction enzymes in combination with DNA ligase help in insertion of genes into plasmid vectors during gene cloning and protein expression. For this, both plasmid DNA containing multiple cloning sites and gene insert are treated with the same restriction enzymes and then glued together with the help of DNA ligase (Fig. 2; Russell and Sambrook 2001). Restriction enzymes are also used after cloning to confirm that insertion of gene has taken place correctly.

### (B) DNA mapping

A DNA map generated by restriction digestion can be used to find the relative positions of the genes. The restriction digestion generates different lengths of DNA which gives a specific pattern of bands after gel electrophoresis. This can be used for DNA fingerprinting.

Additionally, it helps in diagnosis of single nucleotide polymorphisms (SNP) and insertions/deletions (Indels) (Kudva et al. 2004), identification of genetic disorder loci, assessment of the genetic diversity of populations, and parental testing.

### (C) Restriction fragment length polymorphism (RFLP)

Restriction enzymes are used to digest genomic DNA for gene analysis using Southern blot. With the help of this technique, researchers can find copy number of a gene present in the genome of one individual as well as number of gene mutations (i.e., polymorphisms) within a population. The latter is called restriction fragment length polymorphism (RFLP) (Botstein et al. 1980).

### (D) Studying epigenetic modifications

The sensitivity of restriction endonucleases toward methylated bases has been used to map modified bases within genomes. In brief, restriction landmark genome scanning (RLGS) is a 2-D gel electrophoresis-based mapping technique that utilizes *NotI* (GC<sup>^</sup>GGCCGC), *AscI* (GG<sup>^</sup>CGCGCC), *EagI* (C<sup>^</sup>GGCCG), or *BssHII* (G<sup>^</sup>CGCGC) to identify changes in the methylation patterns of the genome of normal and cancer cells.

**Restriction Enzyme,**

**Fig. 2 Workflow of molecular cloning using restriction digestion.** Both gene insert and vector were digested with same restriction enzymes and purified. The insert and vector were joined using DNA ligase and transformed in competent bacteria cell (e.g., *E. coli* DH5a). Colonies were screened for positive clones using restriction digestion with same enzymes or colony PCR or sequencing

**(E) Preparation of DNA libraries**

Restriction enzymes are used in SAGE (serial analysis of gene expression) for identification and quantification of a large number of mRNA transcripts in cancer research to diagnose mutations and study gene expression. Few restriction enzymes including *ApeKI* used to construct the DNA library for a genotyping-by-sequencing technology to study the sequence diversity in genome of organisms (Elshire et al. 2011).

biotechnological approaches have resulted in new face of restriction enzymes with high fidelity and efficiency in their activity. This ultimately eases the work of researcher. Innovative applications of restriction endonucleases have accelerated the development of biotechnology and insight us with new opportunities and challenges.

DNA sample is digested by specific restriction enzymes, and the resulting restriction fragments are resolved according to their size using gel electrophoresis. RFLP was discovered in 1984 by the English scientist “Alec Jeffreys” while working on area of hereditary diseases.

- RFLP acts as a molecular marker and is specific to a single clone or combination of restriction enzyme.
- Majority of RFLP markers are codominant (i.e., both alleles are detected in heterozygous sample).
- It is highly locus-specific.

## Principle of RFLP

RFLP employs the use of restriction enzymes which cut at specific sites on DNA. With the help of a specific restriction enzyme, fragments of DNA are generated which is detected with the help of restriction probes. In RFLP, the length of restriction fragments of a certain type of restriction enzyme differs between individual organisms and species which help to identify and study genetic polymorphism as well as inter- and intraspecific variations.

## Restriction Fragment Length Polymorphism

Reema Chaudhary and Ganesh Kumar Maurya  
Molecular Biology Division, Bhabha Atomic  
Research Centre, HBNI, Mumbai, India

### Synonyms

[DNA typing](#); [Genetic fingerprinting](#)

### Definition

Restriction fragment length polymorphism (RFLP) is a molecular biology tool that reveals the difference between samples of homologous DNA molecules from differing locations of restriction enzyme sites. In this method, the

### How Does RFLP work?

The procedure of RFLP is a multistep process which has been detailed below:

#### 1. Extraction of DNA

RFLP starts with extraction of DNA from different origin like blood, saliva, semen, etc. and purified.

#### 2. Restriction digestion of DNA

In this step purified DNA is digested with a specific restriction enzyme, which will cut DNA into fragments of different sizes along with the specific desired fragments.

#### 3. Separation of DNA fragments using gel electrophoresis

The digested fragments are separated using gel electrophoresis composed of either polyacrylamide or agarose, on the basis of length or

molecular weight. Different size of fragments gives different bands across the length of gel.

#### 4. Denaturation

Once the run is complete, gel is placed in denaturation solution (1.5 M NaCl/0.5 M NaOH) to get single-stranded DNA (ssDNA) which is required for Southern blotting.

#### 5. Blotting

The denatured gel containing ssDNA is placed over charged nitrocellulose or nylon membrane to transfer ssDNA over membrane by capillary blotting or electro-blotting.

#### 6. Cross-linking and blocking

The transferred ssDNA is cross-linked in order to fix in membrane either by baking in vacuum at 80 °C for 2 h (in case of nitrocellulose) or exposure to UV radiation (for nylon membrane). The nitrocellulose paper transferred with DNA is fixed by autoclaving. Further, membrane is blocked with the use of bovine serum albumin or casein to prevent non-specific binding of the radiolabeled probe to the charged membrane.

#### 7. Hybridization and visualization

The radiolabeled RFLP probe which is complementary in nature is hybridized with DNA

present on the nitrocellulose membrane. The membrane is washed several times to remove unbound probes and then processed for autoradiography for visualization of DNA band.

### Applications of RFLP

1. **Genome mapping** – As RFLP gives unique band pattern of genome after restriction digestion, it is used in identification and differentiation of organisms. In addition, it helps to calculate recombination rate which ultimately provides genetic distance between the loci (Menz et al. 2002).
2. **DNA finger printing (forensic test)** – DNA finger printing uses the principle of RFLP which is useful in paternity test, identification of rape victims or other criminals, etc. (Cousins et al. 2000).
3. **Analysis of genetic diseases** – RFLP helps in analysis of genes involved in genetic or hereditary diseases (e.g., cystic fibrosis) among family members.
4. Detection of mutated gene (Fig. 1; Liu et al. 2004).

### Restriction Fragment Length Polymorphism,

**Fig. 1** Schematic representation of steps involved in RFLP for diagnosis of mutation

5. RFLP can be used in analysis of genetic diversity or breeding patterns in plant or animal populations (Wei et al. 2007).

### Demerits of RFLP

1. Being widely used in forensic science, medicine, and genetic studies, RFLP is no longer evident in front of relatively simple and less expensive DNA-profiling techniques like polymerase chain reaction (PCR).
2. The RFLP is a multistep, time-consuming process unlike PCR which can amplify target DNA sequences in few hours.
3. RFLP needs a large amount of DNA sample for analysis whose extraction or isolation is laborious and time-consuming. On the other hand, PCR can amplify very small amounts of DNA in fraction of hour.
4. PCR has replaced RFLP in application requiring DNA sequencing like paternity testing or forensic analysis.
5. The identification of single-nucleotide polymorphisms (SNPs) for analysis of disease status in Human genome project has no more required RFLP.

### Conclusion

Restriction fragment length polymorphism uses specificity of restriction endonucleases to generate different fragment of variable length of DNA samples across different individuals or organisms. Analysis by RFLP played a vital role in genome mapping and genetic disease analysis. With the recent advances in molecular biology and genomics, the use of RFLP has reduced due to slow, costlier, and cumbersome features.

### Retroactive Interference

Paula Alfonso-Arias and Susana Carnero-Sierra  
Universidad de Oviedo, Oviedo, Spain

### Synonyms

[Competing cues](#); [Memory](#); [Paired-associated learning](#); [Retrospective evaluation](#)

### Definition

Retroactive interference arises when a new learning affects a previous recall. For instance, in an experimental procedure, a list of words, A, is presented. After that, a new list, B, is shown. Retroactive interference comes when the learning of the new list (B) affects the recall of the list first presented (A).

### Introduction

A common and annoying effect in learning is when new data modify previous information.

For example, a pregraduate student is sometimes confused when he/she needs to study two lessons, one after the other. When the student tries to remember the first lesson, it is possible that the information of the second lesson interrupts the learning of the first lesson. This situation is clearly stated and summarized in Fig. 1.

**Forgetting: Time Passing or Interference?**

This interference effect is related with the nature of forgetting (Baddeley et al. 2009). The first author interested in the dynamic of forgetfulness was Hermann Ebbinghaus. This scientist, crucial in the study of the roots of memory, drew the forgetting curve (Ebbinghaus 1885) to try to explain how memories vanish along time. Ebbinghaus proposed that to forget is due to the decline of the information by the passing of time.

After Ebbinghaus, theories based in association started to claim the concept of interference as the motor of forgetting (Ruiz-Vargas 2010). According to interference theory, the loss of information is not only due to the passing of time, but could also be caused by different situations and competing cues in the learning process and subsequent memories.

To unravel if forgetting is due to time passing or mediated by other experience interferences, the paradigm of dream and wakefulness was used by memory topic researches. In this procedure, the dream phases are used to induce time lapses without interferences or physiological changes due to learning in wakefulness.

Jenkins and Dallenbach (1924) were pioneers in the use of this paradigm. In their study, students

from Cornell University had to learn series of 10 meaningless syllables. Series were repeated until they were totally learned by participants. When they were able to correctly repeat all the stimuli, the series were later recovered in a 1, 2, 4, and 8 h delay. This recall test could be in a dream condition or in a wakefulness condition. Results showed that forgetfulness was higher in wakefulness than in the dream condition. These data suggested that forgetting was not only caused by the passing of time, but was also influenced by experiences in the wakefulness phase.

Anyway, this procedure has problems because of different levels of processing occurring during sleep, and it is not equivalent to not having experiences on processing. On the other hand, another hypothesis considers that consolidation during dream phase could enhance the recall (Mercer 2015).

**Experimental Paradigm**

If we want to induce an experimental retrospective interference effect in memory, the classic paradigm of the paired-associate learning can be used. In this procedure, a control and an experimental group learn a list of paired words. The first of the pair is the stimulus and the second is called response (for instance, in table-girl, table is the stimulus and girl the response). After the list of associate-paired words was presented, the experimental group is exposed to a second list, in which the stimulus is the same, but the response changes (table-picture, for example). On the contrary, the control group only receives the first list. Both groups are tested at the end of the training. In this test, the stimuli are presented, and the

R

**Retroactive Interference,**  
**Fig. 1** Retroactive interference diagram

**Retroactive Interference, Fig. 2** Example of stimuli for a pair-associated experiment to study retrospective interference

participants have to give the response of the first list. This experimental set reproduces precisely the conditions of retroactive interference (see Fig. 2 for details); therefore, the difference in correct recalls between both groups will measure the effect of retroactive interference.

## Variables that Modulate the Interference

Within the variables implicated in the modulation of interference theory, time interval between the first and the second list presentation can influence interference. Another relevant factor that modulates the strength of information overlap is the similarity of the information. The more similarity in stimuli to recall, the more interference. For example, McGeoch and McDonald (1931) asked their participants to learn a list of adjectives. One group learnt a list and took a rest after for 10 min. The other group learnt the list and another list of different adjectives immediately afterward.

Both groups were tested and asked for the first list. They also manipulated the similarity of the list in the last group and found that the highest forgetting rate was observed when the second list presented synonymous of the first list. This study and others showed that the more similar the material to learn is, the most marked retroactive interference effects are found.

## Retrospective Evaluation

### ► Retroactive Interference

## Retrospective Revaluation

Leyre Castro and Edward A. Wasserman  
The University of Iowa, Iowa City, IA, USA

John Stuart Mill's well-known *Method of Agreement* proposes that if in all cases in which an effect occurs, there is a single prior factor that is common to all of those cases, then it is deemed to be the cause of the effect rather than other rival factors (Mill 1843). So, if on one occasion, a child has an allergic reaction to eating a chocolate bar containing peanuts as well as on a second, later occasion to eating only a package of peanuts, then peanuts would be deemed to be the cause of the allergic reaction; chocolate would be discounted as the cause of the allergic reaction.

To the logician, there is nothing special about the order of causal episodes. The above case of pairing a compound cue (e.g., two foods, let's call them AX, such as peanuts and chocolate) with an outcome (e.g., let's call it "+", an allergic reaction) and then presenting one of the single cues (e.g., peanuts, A) paired with the outcome as well (i.e., AX+ followed by A+), should be equivalent to the case of A+ followed by AX+. In both cases, pairings of one of the cues alone with the outcome (e.g., A+) should lead to weakened causal attribution to the other cue (e.g., X).

However, the leading theory of associative learning during the final decades of the last century – Rescorla and Wagner's (1972) model – makes a striking prediction as to the causal strength of the distinctive factor: namely, X will acquire little strength in the case of A+ followed by AX+, whereas X will acquire and maintain substantial causal strength in the case of AX+ followed by A+. Why? In the case of A+ followed by AX+ (Kamin 1968), according to the Rescorla-Wagner model, A will acquire most of the available causal strength following the A+ experience, leaving little causal strength for X to acquire during the AX+ experience. In the case of AX+ followed by A+, both A and X will acquire substantial causal strength after the initial AX+ experience, and X will maintain that strength because it can neither gain nor lose strength during the later A+ experience, because it is not presented.

But contrary to the Rescorla-Wagner model, considerable empirical evidence suggests that X does indeed lose causal strength when A+ is presented after the initial AX+ pairings (see Chapman 1991; Dickinson and Burke 1996; Shanks 1985; Wasserman and Berglan 1998, for results with humans; see Harris and Westbrook 1998; Kaufman and Bolles 1981; Miller and Matute 1996, for results with animals). The change in the causal strength of absent cue X during A+ training represents a case of *discounting* – a fall in the causal strength of X that is not attributable to experience with X, but rather to experience with A after initial training with AX. In other words, because A is later proven to be the common causal factor, X is retrospectively discounted after having previously been as plausible a causal candidate as A.

Conversely, if the presented cue loses strength in the light of evidence (e.g., presentations of A without the occurrence of the allergic reaction), then nonpresented cue X correspondingly gains strength as well. In other words, subsequent presentations of A alone *without* the outcome lead to strengthened causal attribution to the absent cue – *augmentation*.

These effects – both discounting and augmentation – are instances of the so-called *retrospective revaluation*. People change their causal

evaluations of the cues that are *presented* on an informational trial; however, in the light of new evidence, they also change their causal evaluations of prior cues that are *not* presented on that given trial. The nonoccurrence of an event, as well as its occurrence, can indeed be informative.

Various different theories try to explain retrospective revaluation effects such as discounting and augmentation. We can divide these theories into associative accounts (e.g., Dickinson and Burke 1996; Van Hamme and Wasserman 1994) and normative accounts (e.g., Cheng 1997): associative theories focus on the automatic and mechanistic nature of causal judgments, whereas normative theories focus on their rational and deliberative nature.

As mentioned above, the Rescorla-Wagner model cannot explain those cases in which the value of *absent* cues is modified, as occurs in discounting and augmentation. Each of these effects entails the apparent retrospective revaluation of a cue, something that is not predicted by the original model. Van Hamme and Wasserman (1994) observed that the Rescorla-Wagner model does not consider both the occurrence and non-occurrence of a cue. Only a cue that is actually presented is assigned a learning rate parameter; a nonpresented cue is not entered into any associative process and therefore is assigned a zero value. Instead, Van Hamme and Wasserman suggested assigning different learning rate parameters to presented and nonpresented cues, so that the learning parameter for a present cue is *positive*, but the learning parameter for an absent (but expected) cue is *negative*. This simple modification allows the Rescorla-Wagner model to explain those problematic findings regarding non-presented cues (also see Dickinson and Burke (1996) for a revision of Wagner's (1981) SOP model that can also explain retrospective revaluation effects, and Ghirlanda (2005)).

Normative models explain the different phenomena observed in causality judgments as the result of an inductive reasoning process. For example, Cheng's (1997) theory embraces the following precepts: (a) causes are not merely followed by their effects, but they *generate* those effects; (b) people do not infer a causal relation

between a cue and an outcome unless they know of a specific causal mechanism that connects the cue to the outcome; and (c) people have to determine to what extent the cue influences the probability of the occurrence of the outcome (when all other events are kept constant), taking into account the base rate of the outcome.

Critically, according to Van Hamme and Wasserman's revised Rescorla-Wagner model, in retrospective revaluation situations like the ones described above, both discounting and augmentation should be observed. According to Cheng's theory, only augmentation should be observed; according to Cheng, discounting is not a true effect; people cannot make a judgment in this case, because they lack information about the cues in the absence of the outcome.

Most of the studies that have previously reported discounting and/or augmentation have compared judgments in the discounting condition to judgments in the augmentation condition (e.g., Chapman 1991; Chapman and Robbins 1990; Dickinson and Burke 1996). This experimental design lacks an appropriate control condition; so, it is unclear whether the difference between conditions is due to discounting, to augmentation, or to both effects.

Wasserman and Berglan (1998) included a critical control condition, in which none of the cues initially trained in compound were later presented in the second stage of training. This improvement to the standard retrospective revaluation experimental design allowed them to observe that *both* effects, discounting and augmentation, take place (see also Castro and Matute 2010). Later, Wasserman and Castro (2005) showed that explicit information about the absence of non-presented cues increased their salience, leading to stronger retrospective revaluation effects than when no explicit mention is made about the absence of nonpresented cues, a prediction that follows directly from the revised Rescorla-Wagner model. Cheng's (1997) theory cannot explain either why both discounting and augmentation are observed or why informed absence enhanced the magnitude of both discounting and augmentation. Thus, the empirical observations in relation to retrospective revaluation effects may

be better explained by an associative than by a normative model.

Finally, we should note that retrospective revaluation effects, and cue competition effects in general, have stimulated a fruitful theoretical and empirical exchange between associative learning in nonhuman animals and human causality judgments (Allan 1993; Alloy and Tabachnik 1984; Dickinson et al. 1984; Gluck and Bower 1988; Shanks 1995; Wasserman 1990), an exchange from which both research areas have greatly profited. This productive interchange ought to have hearted David Hume (1777/1951), who deemed the mechanics of causal judgment to apply with equal force to humans and our animal kin.

University, Savannah, GA, USA

## Introduction

Reversal learning has been a widely used procedural paradigm in the field of animal behavior and comparative cognition since its inception in the early twentieth century (Williams 1942). This is, in part, due to reversal learning's relatively simple procedural design, which allows it to be implemented in almost any context, using a variety of apparatuses, and with a potentially limitless array of stimuli. In terms of its efficacy as a research tool, it can be used to measure differences, both within and across species, in the "...adaptation of behavior according to changes in stimulus–reward contingencies" (Clark et al. 2004). This type of overt behavioral change that is evoked by environmental feedback is called behavioral flexibility, which appears to be closely tied to, or an outward expression of, internal levels of cognitive flexibility (Gonzalez et al. 1966). Cognitive flexibility is the ability to shift attention to relevant discriminative stimuli, depending on their effectiveness in optimizing environmental outcomes. In turn, cognitive and behavioral flexibility are believed to be essential components of intelligent and adaptive behavior. The reversal learning paradigm has functioned to advance our understanding of how organisms discriminate between stimuli, as well as how they learn to attend to relevant vs. irrelevant information. It illuminates how organisms utilize environmental

information to predict the probability of future reinforcement, as well as to produce a different behavior or learn new associations when environmental consequences change.

There are numerous iterations of the reversal learning procedure, each of which illuminate important findings on the differences in performance obtained within and across species. Various theories have been proposed as to why these differences occur. These include differences in external pressures, such as an organism's ecology, as well as internal differences in cognitive mechanisms thought to underlie levels of cognitive flexibility, such as impulsivity, inhibition, memory for previous associations, and the learning of new ones. Finally, some possible neurological correlates that may underlie these differences in behavioral change have been identified. Below is a summary of this information.

## Reversal Learning Procedures

The topic of reversal learning can be conceptualized both from a procedural and behavioral viewpoint. This is similar to the idea of extinction, which can be defined procedurally as when responses to a previously reinforced stimulus are no longer reinforced, but behaviorally when the animal stops performing the previously reinforced operant response (Sidman 1988). From the procedural viewpoint, the reversal learning paradigm can be characterized as presenting an organism with an initial phase of simple discrimination learning, where reinforcement is repeatedly paired with a response to one stimulus (e.g., red circle, S1+) and not another (e.g., green circle, S–). At some point, the reward values associated with the two stimuli are reversed (S1–, S2+). Now responses to the previously incorrect stimulus (e.g., green) are reinforced, while responses to the previously correct stimulus are extinguished. Although the procedural transition point is clearly marked by the change in contingencies, from a behavioral point, this transition point is less clear. From the animal's point of view, the feedback associated with the first reversal trial comes after the animal responds. Therefore, the animal will most likely respond

incorrectly on this trial if it is still under the control of the previous contingency. Only after this feedback can the animal adjust to the change. That is, the animal must cease responding to the previous, but no longer reinforcing, stimulus while learning to reliably respond to the previously incorrect stimulus which is now reinforced. The specific point at which the contingencies are reversed typically occur after the subject has achieved some predetermined criterion level of performance; however, researchers have also assigned reversals to occur after a specific number of trials or sessions. Both of these designs have yielded interesting results.

## **Trials to Criterion**

**Simple Comparison Group Design** In a simple comparison group (AB) design using trials to criterion as a marker for reversals, an initial phase of simple discrimination learning is followed by a single reversal phase once the subject begins to reliably respond to the initial S+ while also withholding responses to the initial S-. Reliability of this type is typically operationalized as some criterion level of performance (e.g., 90%) within a block of trials or sessions. At this point, the contingencies are reversed and the number of trials to the same criterion as in the initial phase is plotted as the dependent measure. Rates of reversal learning are measured by the rapidity with which the animal is able to adjust these two behaviors to the appropriate stimuli (withholding responses to S-, responding to S+). Many early, simple comparison group studies focused on the effect of various methodological parameters, such as the number of relevant cues in a discrimination, the complexity of the task, the amount and type of food reward provided to the S+ responses, and the effect of various levels of training on subsequent learning of the reversal problem. In these initial studies, the goal was to theorize about how an animal comes to learn about the relevant cues in the experimental context as well as how the animal learns the appropriate responses to the stimuli attached to those cues.

One major area that attracted attention in the early 1950s was the counterintuitive finding of the overtraining reversal effect (ORE). This effect was discovered by Reid (1953) using a Y-maze apparatus and a black/white visual discrimination in rats. Reid (1953) found that ORE rats given an additional 150 trials on the initial discrimination after reaching criterion learned to switch in about half the time as compared with rats who were given a reversal as soon as they reached criterion. Traditional theories of learning predicted that this overtraining should attenuate reversal learning. The major contribution of the ORE was that it lent support to the attentional theory proposed by Sutherland and Mackintosh (1971), which states, "...reversal learning will be rapid to the extent to which the relevant analyzer is maintained during reversal" (p. 252). Therefore, in order to learn the reversal of any discrimination, the subject must continue to attend to the originally relevant stimulus dimension or cue. This follows that overtraining should be more likely to facilitate reversal learning the more there are irrelevant cues present in the environment. Overtraining results in relevant cues (e.g., brightness) appearing as more salient to the subject while irrelevant cues (e.g., spatial cues) are less likely to be attended (Lovejoy 1965; Schade and Bitterman 1966).

An additional point of interest lies in the behavioral stages of transition often seen in many animals and of interest to theories of flexibility and learning. As Sutherland and Mackintosh (1971) state "Reversal learning can, in effect, be regarded as consisting of two parts: first, the extinction of the original discrimination, and second, the acquisition of the reversal discrimination" (p. 258). These two processes may very well tap into different cognitive mechanisms of learning, with the former dealing with inhibition and extinction learning, and the latter dealing with the learning of new associations. One aspect of the theory that is important is that the cessation of responses to the previously relevant stimulus and the initiation of responses on the previously irrelevant stimulus might be driven by two separate processes. The former being controlled by inhibition to an excitatory response, while the latter could be characterized by exploration for new relationships. The first process appears to deal with the

strength of working-memory for previously learned relationships, while the second process appears to deal with the ability for the animal to learn and seek out new relationships. Both of these processes contribute to the levels of behavioral flexibility that will be demonstrated by a given subject.

Another important aspect to reversal learning is that the animal has to also be able to behaviorally inhibit responses to the previously correct stimulus, which may differ in time from, or be expressed at a different time than, having learned to attend to the relevant dimension. Mackintosh (1975) further added insight to how animals learn to change behavior in the reversal task. His theory centered around attention to relevant “analyzers” or relevant stimulus dimensions (Sutherland and Mackintosh 1971). If the animal was attending to brightness when spatial location was the relevant dimension being manipulated, for example, it would not be able to learn how to maximize reinforcement because it would not be able to discover the functional relationship between spatial location and reinforcement. After repeated trials, of random reinforcement, the animal might shift attention to, or from a more behavioral account, respond based on the spatial dimension (go left, regardless of brightness), wherein it would come in contact with the functional relationship and learning would ensue.

**Serial Reversal Learning Design** One variation in the procedure of the initial reversal learning (AB) design called the serial reversal procedure has been to repeatedly reverse the contingencies over training. In this procedure, specific contingencies remain constant until the animal reaches some criterion level of discrimination performance. Usually this criterion involves choosing the correct stimulus 85–90% over a specified unit, such as a block of trials or sessions (e.g., the last ten trials, two consecutive sessions). Each time the animal reaches this criterion, contingencies reverse. This process (ABABAB...) is typically repeated a handful of times. The dependent measure is usually plotted as the number of errors or number of trials to criterion across reversal blocks. Additionally, a relative measure of reversal learning determines a ratio of errors, for

example, for the initial acquisition divided by the errors demonstrated on subsequent reversal phases. In this respect, the length of time it takes for an animal to initially learn the discrimination can be compared to the errors on the subsequent reversal phases to get a measure of the overall rate of reduction in errors over time. That is, if it takes a pigeon 15 trials to reach criterion and only 5 trials during one of the reversal phases, then the animal has reduced its errors to 33% of its initial error rate, which is the same as if it had taken 30 trials initially and 10 on a subsequent reversal phase.

What is often found is that the first reversal phase shows the greatest number of errors, due to the fact that the history of reinforcement at this point is 100% for S1 and 0% for S2. As reversals recur, the overall percentage shifts to 50%/50%, then 75%/25%, and so on, constantly evening out the long-term values of the two stimuli. What ends up becoming important, or what provides the most information about the functional relationship, is the most recent experience with reinforcement and the associated response (Rayburn-Reeves et al. 2013). The more an animal can both detect and react to this event, while ignoring the overall value of the stimuli, the more efficient they will be in maximizing reinforcement.

The reversal learning paradigm began to grow in popularity around the middle of the twentieth century, when it appeared that this paradigm could be used to classify different species according to their level of improvement across reversals as an indication of their level of general intelligence. This was, in part, due to the work of Harry Harlow (1949), who studied a variety of species on a similar procedure to reversal learning, called an object quality discrimination task. In this task, the animal is presented with two novel stimuli, such as a star and a circle, where the values of these stimuli are randomly assigned as S+ and S−. In this respect, the animal could not predict which stimulus would be rewarding on Trial 1, but regardless of which stimulus the animal chose, the outcome of the response should provide all the information the animal would need in order to choose optimally on subsequent trials. The animal would be presented with six trials of this same

object-pair contingency and would then be presented with a novel pair of images, randomly assigned in value. What Harlow found was that species differed over learning in their ability to choose optimally on Trial 2 of each new problem, with some primate species performing above 90% on Trial 2, while other species, such as squirrels, cats, and rats, showing poorer performance on these trials. Harlow discussed these differences in performance as differences in the ability to develop a *learning set*, which he defined as "...learning to learn from a situation an animal frequently encounters" (Harlow 1949). It appeared that some animals could learn a general rule based on reinforcement contingencies that could be applied to all objects, regardless of their novelty (Harlow 1949; Schrier 1984). Based on this finding, the serial reversal learning task became a popular paradigm for studying the relative changes in behavior over reversals which served as a measure of behavioral flexibility across species.

Since the initial experiments in the early twentieth century, beginning with Buytendijk (1930) using a position/spatial discrimination and Krechevsky (1932b) using a brightness discrimination, the main finding in serial reversal learning tasks is that, over repeated reversals of the discrimination, the animal learns to switch responses to the presently reinforced stimulus with increasing rapidity, sometimes resulting in a single trial needed to show the reversed behavioral responses (Dufort et al. 1954; Mackintosh et al. 1968). This behavioral pattern has been termed rapid reversal learning, where the animal only has to be exposed to a few instances of the reversed contingency to shift to the appropriate strategy (Lionello-Denolf 2013). Like Harlow (1949), researchers began studying a variety of species on the SRL task, noting differences in the ability of certain species to reduce the number of errors before reaching criterion across reversals (Behrend et al. 1965; Bitterman 1965; Gonzalez et al. 1966; Mackintosh 1963, 1971; Mackintosh and Holgate 1969; Mackintosh et al. 1968; Schade and Bitterman 1966). Bitterman's (1965) research led him to conclude that there were qualitative differences in the way certain species solved the

task, while Sutherland and Mackintosh (1971), Mackintosh (1975) argued that the differences in learning rate were not qualitative, but quantitative, suggesting the same mechanism for learning was involved, but some species were quicker to change behavior than others.

Other researchers, such as Warren (1964), however, began pointing out the issues in procedural differences that could account for the performance differences seen. When trained under optimal conditions, many species that had previously shown no improvement across reversals now showed significant improvement. A number of factors, such as sensitivity to the dimension being tested, discriminability of the dimension being tested, relationship of discriminative stimuli to complexity in the environment, the relevance of the stimuli to survival, and other competing sources of information present during learning, could influence the rate of learning in reversal tasks as measured by sensitivity to changing reinforcement contingencies. These findings complicated the interpretation of prior results, leading researchers to move away from the reversal paradigm as a way of assessing general intelligence levels across species.

Due to the reversal event being contingent on the animal's performance, the varying point of reversal that occurs when using trials to criterion as a marker for the reversal event appears to create a situation where the recent response-reinforcement contingency provides the most relevant information about future reinforcement. Reversals occurring in consistent, fixed, units result in the increase in value of other sources of predictive information.

### Fixed Time or Trial Number

Another way to present reversals is by fixing or actively manipulating the number of trials before a reversal occurs. Here, the reversals occur independently of the animal's performance. One benefit of this procedure, therefore, is that the experimenter has control over when and how many reversals to which the animal is exposed. The potential drawback is that the animal's performance, then, may

vary widely before each reversal. Low accuracy (or high numbers of errors) would indicate a lack of control by relevant discriminative cues, which could complicate the interpretation of error rate over time. However, if the reversals are on a fixed schedule of time, animals learn to anticipate the reversal and are better able to discriminate the time at which a given response will result in reward (Rayburn-Reeves and Cook 2016). If reversals are on a variable time (or number) schedule, the value of using time as a source of information is weakened, and often eliminated, while the recent history of reinforcement is strengthened. Depending on how salient temporal cues are, as well as their effectiveness in contrast to other cues, such as working memory for most recent response-reinforcement contingency, the animal may show control by one cue or the other.

**Serial Reversal Learning: Reversing Mid-session** Some of the first studies using fixed reversal locations presented reversals across sessions, such as every other day or every few sessions (Gonzalez and Bitterman 1968). These studies showed that pigeons eventually began sessions at chance, quickly learning the relevant discrimination within the session. Very few reversal tasks were conducted with fixed trial number in the mid-twentieth century; however, more recent research has used highly predictive reversal events to compare relative strengths of various discriminative cues on optimizing behavior. For example, in a midsession reversal procedure using a simple simultaneous discrimination task, two stimuli are presented at the same time, such as a red (S1) and a green (S2) key light. In this scenario, one stimulus is correct for the first half of a session (S1+, S2−) while the other stimulus is correct for the last half (S1−, S2+).

In the initial experiments on midsession reversal learning (Cook and Rosen 2010; Rayburn-Reeves et al. 2011), every session began with S1+ and ended with S2+ and the reversal always occurred in the middle of the session (e.g., Trial 41 of 80). This procedure produces consistent patterns of behavior both within and across sessions, where animals, such as pigeons, rats, dogs,

rhesus macaque monkeys, and humans, learn to respond at a high rate to the S1 and S2 stimulus at the beginning and end of every session (McMillan et al. 2014; Laude et al. 2014; Rayburn-Reeves et al. 2013; Rayburn-Reeves et al. 2017). What is interesting is the pattern of behavior that occurs near the reversal location, which has been shown to differ both between and within species under various experimental methods.

For example, pigeons have been shown to produce systematic increases in responses to the S2 stimulus before the reversal occurs, as well as continuing to maintain responses, although at a decreasing rate, to the S1 stimulus after the reversal occurs. This pattern of data suggests that the predictability of the reversal location increased attention to, or made more salient, the temporal cues associated with the reversal event. A series of studies confirmed that pigeons were basing responses on the passage of time within each session based on a reference memory for the reversal event over sessions (ref).

Other recent research has shown that reversal learning performance can be affected by the stimulus modality, such as the use of visual or spatial discriminations, the apparatus (McMillan et al. 2014), the addition of external visual cues, such as colored screens or houselights (Rayburn-Reeves et al. 2016) during the intertrial interval, the presentation of the stimuli (i.e., simultaneous or successive), and the length of the intertrial interval. This research has illuminated how various cues come to exert control over behavioral choice depending on their predictive value for future reinforcement, as well as their level of salience as compared to other available, relevant cues. In pigeons, it appears that time as a cue is quite salient and persistently acquires control over behavior, unless other external cues eliminate the need for timing. Even then, studies have shown that time is still attended to by pigeons, as when the external context cues are removed, pigeons revert to making time-based errors around the reversal location, as if they had been timing throughout the session. Other species such as rats (McMillan et al. 2014) and dogs (Laude et al. 2016) have also been shown to produce marked anticipation and perseveration errors, similar to pigeons.

Although time maintains control over reversal performance in pigeons, dogs, and rats under some conditions, in others it appears to take a back seat to recent response-reinforcement contingencies. One commonality about reversal learning tasks in general is that the recent history of reinforcement provides, almost exclusively, the most predictive and effective information about what response will be reinforced on the following trial than any other cue (with the exception of context cues). If an animal is able to utilize the recent history of reinforcement as a cue, it will receive reinforcement on every trial except the reversal trial. Behavioral patterns that are generated by reinforcement cues sometimes vary in the number of perseverative errors demonstrated by different species, but they typically do not show the anticipation errors, which are indicative of time-based control.

In an initial study by Rayburn-Reeves et al. (2013), rats were shown to display highly adaptive behavior after being trained on a spatial midsession reversal task using lever presses in an operant setup. They also showed consistently high accuracy when reversals occurred in unpredictable locations across sessions, and when multiple reversals were presented in individual sessions. Smith et al. (2016) also found highly accurate performance by rats using nose-poke or lever pressing responses in spatial discrimination tasks. Pigeons have shown similar performance when both visual and spatial discriminations are confounded (McMillan et al. 2014), as well as when the ITI is very short (i.e., 1.5 s) and the discrimination is spatial (Laude et al. 2014). Finally, pigeons have been shown to utilize color cues presented during the ITI that signal which stimulus will be rewarded on the following trial, which result in a lack of anticipation errors and a significant reduction in perseverative errors.

By far, the most efficient behavior has been shown by humans (Rayburn-Reeves et al. 2011), who almost always show a pattern of win-stay, lose-shift responding (Levine 1975). This pattern, where responses to a stimulus that were reinforced on the preceding trial are repeated, while unrewarded responses are not repeated, has been argued to be dependent on the development of a higher-order cognitive process of rule-based learning.

## Neuroscientific Evidence for Reversal Learning

Reversal learning has moved into the psychopharmacological and neuroscience fields where researchers study the effects of various NTs, such as dopamine and 5-HT (serotonin), on errors in the reversal task (Costa et al. 2015; Grandy and Kruzich 2004; Murray et al. 2008). Studies have implicated that these two NTs are critical to reversal learning performance. Both serotonin and dopamine have been shown to have dissociative and selective roles in the reversal learning process (den Ouden et al. 2013). Dopamine has also been shown to be specific to reward-related learning and behavioral flexibility. Too much or too little dopamine can be detrimental to performance on the reversal learning task (Clark et al. 2004).

The reversal learning task has been studied in human subjects to ascertain its relationship to neurobiological mechanisms and underlying neural correlates of behavior. Findings suggest that neural coding has much to do with performance pertaining to the reversal learning task, especially in the frontal lobe (Dargis et al. 2017; Izquierdo and Jentsch 2012). More specifically, it has been suggested that the lateral orbitofrontal cortex (OFC), as well as the ventromedial and lateral prefrontal cortex (PFC) play a critical role in decision-making, inhibitory control, affective responding, and stimulus-reward learning; all of which are processes affecting reversal learning performance (Fellows and Farah 2003; Hampshire et al. 2012; Xue et al. 2013).

The cognitive ability to learn a reversal is also contingent upon age. Younger subjects consistently perform better on the task when compared to older animals (Kovalchik and Allman 2006). Studies have implicated other brain regions in reversal learning as well, and headway has been made in attempts to identify the purpose of these regions in the learning process. More research is needed to further corroborate these findings, but they reflect a shift in reversal learning toward a neuroscientific focus.

### Definition

“Ribosome is a tiny granular cellular organelle that floats freely in cytoplasm as well as attached with the endoplasmic reticulum and performs translation (Protein synthesis).”

# Introduction

The word “ribosome” originates from ribonucleic acid and Greek word soma, which means body (Bakowska-Zywicka and Tyczewska 2009). Albert Claude gave the term “microsome” after his excellent work of cell fractionation in the 1930s. Later, his two students – Philip Siekevitz and George Palade worked on the morphological and biochemical analysis of the secretory process related to the “microsome.” Further, Zamecnik’s group correlated microsome with protein biosynthesis and finally, Richard Brooke Robert in 1958 gave the term “ribosome” (Bakowska-Zywicka and Tyczewska 2009).

The ribosome is a cellular structure which helps in protein synthesis. The mystery of life is stored in the genome sequence of their deoxyribonucleic acid (DNA). The genetic information of DNA is made available by transcription of genes to messenger ribonucleic acid (mRNA) that are subsequently translated into the various amino acid sequences, which are the building block of proteins. The ribosome plays a central role in the biogenesis of proteins from mRNA. The biogenesis of ribosome occurs in nucleoli. The nucleoli are nuclear domains, which are specialized in the production of ribosomal subunits (Stepinski 2014).

# Structure of Ribosome

Thomas Steitz started the work on the structure and functions of the ribosome in 1990s and finally,

in 2000 obtained a high-resolution structure of ribosome. Afterwards, other researchers were able to study the structure of the different subunits of ribosome as well as molecular interaction between them (Zhao 2011).

Ribosomes are composed of RNA and protein. It has two subunits consisting of approximately two-third RNA and one-third protein. Ribosomes from mammalian mitochondria are exception, in which the ratio of protein and RNA is reversed (Sharma et al. 2003). Prokaryotic ribosome (70S) contains a smaller subunit (SSU) 30S and a larger subunit (LSU) 50S. The SSU (30S) is composed of one 16S ribosomal RNA (rRNA) containing around 1600 nucleotides and 20 ribosomal proteins (r-proteins), while the LSU (50S) contains 23S rRNA sequence of 2900 nucleotides, 5S rRNA sequence with about 120 nucleotide and 33 r-proteins (sum total ~4620 nucleotides of rRNA and 53 r-proteins of the bacterial 70S ribosome), where S stands for the Svedberg unit for sedimentation velocity. Compared with the prokaryotes, eukaryotic 80S ribosomes also contain a SSU (40S) and a LSU (60S). The SSU (40S) is composed of one 18S ribosomal rRNA containing about 1753 nucleotides and 32 ribosomal proteins (r-proteins), while a LSU (60S) has 5S rRNA containing sequence with about 120 nucleotides, 5.8S with about 154 nucleotides, and 28S r RNAs with about 3354 nucleotide along with 47 r-protein (sum total ~5381 nucleotides of rRNA and 79 r-proteins of the yeast 80S ribosome) (Fig. 1) (Wilson and Daudna Cate 2012; Ramakrishnan 2009).

**Ribosome, Fig. 1** The simplified structure of prokaryotic and eukaryotic ribosome

**Ribosome, Fig. 2** All three RNA- binding sites on a ribosome

### Function of Ribosome

The ultrastructure of prokaryotic ribosome revealed that it has three tRNA binding sites namely Aminoacyl-tRNA binding site (A site), Peptidyl-tRNA binding site (P site), and Exit site (E site). In the biosynthesis of protein, aminoacyl-tRNA bind to A site during elongation process, whereas at P site the tRNA linked to the growing polypeptide chain is bound. Further, E site provides the binding site for tRNA (Fig. 2).

In prokaryotes, biosynthesis of protein begins by the establishment of a 30S complex between the 30S subunit, mRNA, initiation factors, and aminoacylated tRNA. The 30S subunit binds to specific sequence of mRNA (Shine-Dalgarno sequence) which is situated upstream to the AUG start codon and its complementary sequence is present on the 16S rRNA of the small subunit. The ribosome then changes its own position in a 3' direction with the mRNA till meeting with the start codon. After that large subunit (50S) binds to the 30S initiation complex to form the 70S initiation complex. In this complex, anticodon of AUG is paired in the P site, and further this initiation complex encounters again with other codons and protein synthesis takes place unless the stop codon is encountered.

In eukaryotes the assembly and the protein synthesis process is complex than prokaryotes. Initiation of protein synthesis is basically similar in prokaryotes and eukaryotes except the involvement of initiation factors. Some

important differences between the protein biosynthesis of prokaryotes and eukaryotes are the initiating amino acid is methionine in eukaryotes while *N*-formylmethionine in prokaryotes, eukaryotic mRNA is monocistronic while polycistronic mRNA in prokaryotes. Eukaryotic mRNA does not contain Shine-Dalgarno sequence like prokaryotes therefore initiation codon is recognized by ribosomal scanning of mRNA. Initiation of protein biosynthesis in eukaryotes involves the formation of 48S pre-initiation complex between the small subunit (40S), mRNA, initiation factors, and start codon. The ribosome then scans the mRNA to locate the start codon. Further, the large subunit (60S) binds to form complete 80S initiation complex. Further, this initiation complex encounters again with other codons and protein synthesis takes place unless the stop codon encounters like prokaryotes.

### Summary

The ribosome is a cellular structure which involves in protein synthesis. The transcribed mRNA associate with ribosome and protein synthesis occurs according to the codon of mRNA with the help of tRNA and accessory factors. Thus, in prokaryote, 70S ribosomes and in eukaryotes 80S ribosome play role like protein-making machines.

## Richard Byrne

Richard W. Byrne  
Centre for Social Learning and Cognitive  
Evolution, School of Psychology and  
Neuroscience, University of St Andrews,  
St Andrews, Scotland, UK

## Early Life and Educational Background

Richard “Dick” Byrne was born on 13 August 1950 in London, UK. He attended Hampton Grammar School and went on to St. Johns College, University of Cambridge, to read physics within a Natural Sciences degree. Discovering the excitement of psychology, he switched focus and specialized in cognitive psychology, completing

an undergraduate research project under supervision of Donald Broadbent. Another strong influence was John Morton, who supervised Byrne for his PhD (*Memory in Complex Tasks*, 1976) at the Medical Research Council’s *Applied Psychology Unit*, Cambridge.

## Professional Career

Byrne gained a lectureship at University of St Andrews in 1976 and has remained there all of his career. He has authored more than 150 journal papers and 70 book chapters, in addition to writing *The Thinking Ape* (Oxford University Press 1995; Japanese translations 1998; Chinese translation 2006) and *Evolving Insight* (Oxford University Press 2016; Japanese translation forthcoming) and co-authoring the two *Machiavellian Intelligence* volumes with A. Whiten (Oxford University Press 1988, Cambridge University Press 1997; Japanese translations of both, 2004).

Byrne’s work has been cited more than 17000 times, and he has an h-index of 58. His first book, *The Thinking Ape*, was awarded the Book Prize of the British Psychological Society in 1997. Byrne was awarded the Wright and Hughes Prizes of St Johns College, Cambridge, a Medical Research Council Postgraduate Scholarship, a Development Fellowship of the Association of Commonwealth Universities (held at Auckland University, NZ), and leadership of a Focus Group at the Collegium Budapest, Hungary. He was elected Fellow of the Royal Society of Edinburgh in 2002.

## Research Interests

Byrne’s PhD work developed methods for studying the use of memory in everyday planning tasks. At that time, most cognitive psychology was based on a set of heavily used laboratory paradigms and tended to ignore ordinary human behavior. But when Byrne came to St Andrews, he joined a psychology department with an unusual number of researchers studying animal behavior and discovered that ethology already

had a well-developed approach that meshed natural behavior with controlled experiments.

That led to a move into primate behavior: William McGrew, then at Stirling University, invited him to work on baboons at a site in Niokolo-Koba National Park, Senegal, where he studied how long-range vocalizations are used to coordinate the frequent fission and fusion of ranging baboon parties, thus minimizing predation risk. A collaboration with Andrew Whiten at St Andrews followed in the early 1980s, setting up a field site to study baboon behavioral ecology in the Drakensberg Mountains, South Africa. The project showed how the food constraints of high altitude caused baboons to switch social organization from multi-male groups to small harems. Unexpected observations of baboon tactical deception there led to a data-mining and survey study of primate deception in general: when analyzed in the early 1990s, these data pointed to primate abilities that were not matched in the laboratory until 20 years later, including evidence of theory of mind understanding in (all) great ape species, and geometric perspective-taking ability in Old World monkeys and apes. Byrne's research on monkeys continued through supervision of PhD students, working on spider, howler, and titi monkeys in Central and South America, and vervet monkeys and baboons in Africa. A particular focus was on primate spatial navigation and ranging, leading to the development of a new method of analyzing ranging routes of animals, the "change point test." With Rahel Noser, Byrne showed that the mental maps of baboons, just like those of people, were non-Euclidian, and well described by the concept of a "network-map" – a cognitive model which Byrne had originally developed on the basis of human error patterns he had studied in the 1970s!

The major focus of Byrne's work, on the cognition of African great apes, began fortuitously. Getting to know Professor Toshisada Nishida, who was then visiting McGrew in Scotland, led to an invitation to study chimpanzees in Tanzania; and getting to know Dr Dian Fossey led to her encouragement to work on the famous mountain gorillas in Rwanda. Working on apes allowed Byrne to benefit from his early training in human

cognition, in particular recognizing the hierarchical organization of their complex skills – such as chimpanzee tool-use and the elaborate multistage plant processing that Byrne discovered in gorillas. He found that individual apes were able to construct new routines of skilled manual behavior, using observational as well as individual learning, just as humans do. Byrne developed a cognitive model of how such imitation would be possible, without involving the intentional capacity to read the mental states of the demonstrator – "Behavior Parsing" – a theory that meshes well with the Rizzolatti/Arbib account of mirror neurons as an automatic system of action-understanding which was being developed at the same time. The complexity of the natural plant-processing of mountain gorillas also allowed Byrne to recognize that while strong laterality (hand preferences) developed in individuals as a result of task complexity, population laterality (handedness) was elicited more by the need for bimanual, asymmetric processing – as shown, for instance, when we grip a jar and twist the lid with the other hand. As with theory of mind, these findings from observational data have subsequently been corroborated in the laboratory.

Working with a number of PhD and postdoctoral students, Byrne has studied the natural gestural communication of great apes since the 1990s, a project that now includes orangutans, gorillas, bonobos, and chimpanzees. Their findings confirmed the highly intentional nature of gestures and their careful targeting of gesture modality to the intended audience's attentional focus – and went beyond earlier work in showing that apes take account even of the audience's degree of understanding in selecting their gestures. All species studied have proved to use very large repertoires of gesture types, and these "lexicons" are extensively shared, not only between different populations of the same species but also between different ape species; specific intended meanings as well as gesture forms are shared across species. Byrne's group interprets these patterns to be a result of an innate potential in each ape species to develop the set of gestures used under species-typical natural circumstances (a potential that was "phylogenetically

ritualized” during evolution within the great apes). Young apes explore their innate potential repertoire and its uses, rapidly increasing their active set of gestures and often using whole sequences of gestures with similar meanings, before this repertoire is finally pruned to a smaller number of gestures in the final adult state. Other gestures, in the adult’s potential or passive repertoire, are not totally lost but can be “primed” by seeing another use them. This gives rise to the phenomenon of gestural imitation, in which the copies often vary from the original model – because they are in fact not imitations, but evocations of pre-existing gestures seldom or never used by the adult.

Byrne has long believed that an exclusive focus of comparative and evolutionary psychology on species most closely related to the human – that is, the primates – would be unfortunate, as it is through convergences in distantly related species that we can learn the original adaptive function of cognitive capacities. He has taken several opportunities to turn this idea into concrete results. He worked with Mike Mendl and Susanne Held on the cognition of the domestic pig, modifying experiments first used with apes; they showed that pigs have the ability to take account of some of the knowledge as well as the likely reactions of others in competitive situations. He and Lucy Bates worked with members of the Amboseli Trust for Elephants, analyzing existing narrative records of elephant abilities and devising field experiments to test hypotheses generated from that analysis. They found that elephants possess high levels of empathy for others; that they subcategorize humans into types, reacting distinctively even to indirect cues of a particular human “tribe”; and that they show powerful working memory abilities, perhaps in excess of human working memory capacity, when they keep track of out-of-sight individuals in wide-ranging family groups, picking up cues from identifying individual scents among other cues. Most recently Byrne has collaborated with Martin Whiting and colleagues in studying the cognition of social Australian lizards of the *Egernia* group. Selected publications that illustrate each research topic are shown in Table 1.

**Richard W. Byrne** is Emeritus Professor at the University of St Andrews, Scotland. He is best known for his work on primate cognition in the wild, especially in gorillas and chimpanzees, but has also carried out research on baboons, domestic pigs, and African elephants.

## Richard Dawkins

Elena Racevska

Department of Social Sciences, Faculty of Humanities and Social Sciences, Oxford Brookes University, Oxford, UK

## Main Text

Richard Dawkins (born March 26, 1941, in Nairobi, Kenya, as Clinton Richard Dawkins) is a British evolutionary biologist, ethologist, and author. He is an Emeritus Fellow of New College, University of Oxford. Since 1997, he has been a fellow of the Royal Society of Literature (FSRL). In 2001, he was elected fellow of the Royal Society (FRS).

## Education

Dawkins attended Oundle School in Northamptonshire from 1954 to 1959. In 1962, he graduated Zoology at Balliol College, University of Oxford. Under the supervision of Nikolaas Tinbergen, one of the pioneers of animal behavior research and a Nobel Prize winner (Burkhardt 2010), he continued his study, receiving a PhD in 1966. He stayed as Tinbergen's research assistant until 1967. At the time, his own research interests focused on animal decision-making, on which he has published several papers (Dawkins 1969a, b, c; Dawkins and Impekoven 1969).

## Academic Career

Richard Dawkins began his teaching career in 1967 as an assistant professor of Zoology at the University of California, Berkeley. He stayed at this position until 1969, when he returned to University of Oxford as a senior research officer at the Department of Zoology. In 1970, he became a lecturer in Animal Behavior and a fellow of New College, University of Oxford. He became a reader in Zoology in 1990. In 1995, he was appointed the Simonyi Professorship for the Public Understanding of Science, the chairmanship created specifically for him by a donation from Dr. Charles Simonyi. The aim of the professorship is "to contribute to the understanding of science by the public" (Simonyi 1995). Dawkins held this position until 2008 (Richard Dawkins Foundation for Reason and Science 2015).

Dawkins has edited several peer-reviewed journals. From 1972 to 1973, he was the European editor of "Animal Behaviour Monographs." Between 1974 and 1978, he was the European editor of "Animal Behaviour." In 1983, he became an executive editor of "Oxford Surveys in Evolutionary Biology," which he remained until 1986. In 2002, he founded the "Episteme Journal." He edited "The Oxford Book of Modern Science Writing," an anthology of scientific writings from a variety of authors on diverse of topics, published in 2008. Dawkins has been a member of over 15 committees and has

given over 60 invited lectures across the world. In 1997, he presided the Biology section of the "British Association for the Advancement of Science".

In 1999, Dawkins set up "The Simonyi Lectures." This annual event open to everyone aims "to promote the public understanding of science" (The Oxford Simonyi Professor for the Public Understanding of Science 1999). Over the years, many influential scientists were invited to present on a topic of their choice: Daniel Dennett (1999), Richard Gregory (2000), Jared Diamond (2001), Steven Pinker (2002), Martin Rees (2003), Richard Leakey (2004), Carolyn Porco (2005), Sir Harry Kroto (2006), and Sir Paul Nurse (2007). After Dawkins retired from the position in 2008, the lectures continued under the organization of the new Simonyi professor, Marcus Du Sautoy. Richard Dawkins gave a talk in 2008 and was followed by Timothy Gowers (2009), Christoph Koch (2010), David Spiegelhalter (2011), Luc Steels (2012), Eric Weinstein (2013), David McKay (2014), Melissa Franklin (2015), and Simon Baron-Cohen (2016).

## Publications

Dawkins has authored and co-authored more than 80 small books and peer-reviewed articles. His work has been published in highly cited international journals, such as *Animal Behaviour*, *Behaviour*, *Evolution*, *Nature*, *Science*, and many others. But despite his long-lasting academic career, Richard Dawkins is best known to the general public for his books on evolutionary biology, many of which have been translated in multiple languages and have become bestsellers.

In 1976, he published "The Selfish Gene" (Dawkins 1976). In this book, Dawkins explores the biology of selfishness and altruism, explaining a gene-centered view of evolution, which is in contrast to the organism- or group-centered views developed by scientists such as William D. Hamilton in the 1960s. According to this view, the more the two organisms are genetically related, the more beneficial will it be for them to behave selflessly toward each other, as this will maximize their inclusive fitness. Dawkins

explains that genes' selfishness is a metaphor, as genes that are replicated are those whose evolutionary consequences serve their own implicit interest, and not necessarily the interest of the organism that carries them. This book is also known for the first mention of the term "meme," coined by Dawkins to mean a unit of human cultural evolution, analogous to the gene. This book became a bestseller and has been translated into over twenty-five languages.

In 1982, Dawkins published "The Extended Phenotype." This book, which he considers his principal contribution to evolutionary theory, discusses the idea that phenotype is not limited to biological processes but should be extended to encompass all effects that a gene has on its environment, both inside and outside of the individual organism that contains it (Dawkins 1982). Dawkins explains three types of extended phenotypes. The first type refers to animals' capacity to modify their environment through the use of architectural constructions and by that increase their fitness. The second type is the so-called parasite manipulation, and it involves parasites' manipulation of hosts' behavior, for the purpose of creating distinct advantages for their own fitness. The third type is the parasitic manipulation of host behavior without being physically associated with the host (e.g., as with the chicks of cuckoo birds). In this book, Dawkins also introduced the "Central Theorem of the Extended Phenotype," which postulates that animal's behavior tends to maximize the survival of the genes "for" that behavior, whether or not they happen to be in the body of the animal performing said behavior.

Dawkins's next book, "The Blind Watchmaker," was published in 1986. Herein, Dawkins presents the argument for the theory of evolution by natural selection. He explains the unintentional nature of evolution by making a reference to William Paley's "watchmaker analogy," made famous in Paley's 1802 book "Natural Theology." Also known as "the watchmaker argument," this teleological argument states that design implies a creator. Dawkins, however, contrasts the planning potential of human design to the accumulation of random mutations, likening the evolutionary processes of natural selection to a blind watchmaker

(Dawkins 1986). In 1987, Dawkins was awarded the "Royal Society of Literature Award" and the "Los Angeles Times Literary Prize" for this publication. The same year, a documentary carrying the same name was released. Written by Jeremy Taylor and presented by Dawkins, it won the "Sci-Tech Award for Best Science Documentary" of the year.

In 1995, Dawkins published "River out of Eden: A Darwinian View of Life." In this book, Dawkins uses a metaphor of a river flowing through time (instead of space) to discuss descent, heredity, and speciation (Dawkins 1995). He debates about the last common ancestor of all living humans – the "Mitochondrial Eve." Moreover, he asserts that the key feature of evolution is its gradualness.

The following year, Dawkins published "Climbing Mount Improbable." This book, in which he discusses the applications of probability on evolution, was developed from the ideas Dawkins discussed in his series of lectures entitled "Growing Up in the Universe," written and recorded in 1991 as a part of "Royal Institution Christmas Lectures." Designed to debunk creationists' claims about natural selection, the main metaphor used in "Climbing Mount Improbable" is that of a geographical landscape, which Dawkins uses to explain how seemingly complex mechanisms develop from many gradual steps (and not from "climbing cliffs") (Dawkins 1996). This visualization of the relationship between genotypes and reproductive success is also known as an adaptive or fitness landscape. In this metaphor, fitness is represented as landscape's "height," and genotypes that are similar are visualized as "close" to each other. This idea is also used to explain flawed forms in evolution by natural selection, such as animals' reactions to supernormal stimuli.

In 1998, Dawkins published "Unweaving the Rainbow," subtitled "Science, Delusion and the Appetite for Wonder." In this book, he battles the stereotype that scientists such as himself deprive life of meaning and argues that they see it as full of wonders and pleasures that arise from the understandable laws of nature (Dawkins 1998). He discusses the relationship between

science and the arts from a scientist's perspective, using different examples to illustrate how artists and scientists are motivated by the same spirit of wonder. He argues that unfolding mysteries leads to even more exciting ones. Throughout the book, Dawkins exemplifies how scientific methods can be used to detect and correct the fallacies that can arise from a lack of statistical reasoning, such as over-interpretation of coincidence. Dawkins also discusses the selfishness of cooperation. Bringing it down to a genetic level, he explains coadaptation and coevolution as two contexts of collaboration through which genes compete.

In 2003, Dawkins published a book of selected essays and other writings entitled "A Devil's Chaplain" (subtitled "Reflections of Hope, Lies, Science, and Love"). The title is a reference to Charles Darwin's quotation on his lack of belief in "a perfect world" designed by God: "What a book a devil's chaplain might write on the clumsy, wasteful, blundering low and horridly cruel works of nature!" (The Guardian 2003). The topics he discusses in this publication range from evolutionary biology, scientific methods, memes, ethics, and religion. The book also includes chapters on some of Dawkins's "heroes," such as Douglas Adams, W.D. Hamilton, John Diamond, Richard Leakey, and Stephen Jay Gould. The book ends with a letter Dawkins wrote for his then 10-year old daughter, Juliet. In this letter, he spells out the importance of evidence as basis of knowledge, encouraging her to always look for and value evidence over "tradition, authority or revelation" (Dawkins 2003).

Dawkins published his longest book to date, "The Ancestor's Tale: A pilgrimage to the Dawn of Life," in 2004. This book, nominated for the 2005 Aventis Prize for Science Books, follows a backward path of human evolutionary history, meeting humanity's cousins and their last common ancestors (or "Concestors," as Dawkins calls them, using the term coined by Nicky Warren). Making a notion that patterns recur and evolution rhymes (in reference to a quote on history, attributed to Mark Twain, which says that history does not repeat itself, but it rhymes), Dawkins discusses the predictability of evolution. Using a backward chronology all the way to the grand

ancestor of all surviving life forms on Earth, Dawkins celebrates equality of all species and unity of life (Dawkins 2004).

Richard Dawkins is broadly known for his openly antireligious views. Although often regarded as the most famous atheist in the world, he declared himself as agnostic in his 2006 book "The God Delusion." In this book, which sold in over one million copies, Dawkins uses multiple examples to explain the nonnecessity of religion for morality. He asserts the near certainty of non-existence of a supernatural creator and declares a persistent belief in a personal god to be a delusion, due to its stronghold against the rich contradictory evidence (Dawkins 2006). This book has been translated into 35 languages, and many books have been written in its response (Dawkins 2015).

In 2009, Dawkins published "The Greatest Show on Earth: The Evidence for Evolution." The title of this book comes from a T-shirt quote, anonymously sent to Dawkins, which read "Evolution, the Greatest Show on Earth, the Only Game in Town" (Dawkins 2009). This publication contains succinct discussions of multiple explicitly set out evidence for biological evolution, from the artificial selection to the fossil record. Despite previously having written numerous publications on this topic, Dawkins considers this book to be his "missing link," and a "personal summary of the evidence that the 'theory' of evolutions is actually a fact – as incontrovertible a fact as any in science" (Dawkins 2009, p. vii).

Dawkins has also written books for children and young adults. In 2011, he published "The Magic of Reality: How We Know What's Really True" (Dawkins 2011). This graphic book, illustrated by Dave McKean, comprises retellings of multiple creation myths from all over the world, both traditional and contemporary. It also includes Dawkins's recollections of his own childhood thoughts on various phenomena. Some of the topics include atomic theory, planetary motion, gravitation, stellar evolution, spectroscopy, plate tectonics, exobiology, and human psychology.

In 2013, Dawkins published an autobiographical memoir entitled "An Appetite for Wonder: The Making of a Scientist" (Dawkins 2013). In this book, Dawkins talks about his first 35 years,

his life before “The Selfish Gene.” The second volume of his autobiography, “Brief Candle in the Dark: My Life in Science,” was published in 2015 (Dawkins 2015). In this publication, he discusses his ideas, inspirations, and “heroes,” from Charles Darwin to Peter Medawar, Nikolaas Tinbergen, William D. Hamilton, John Maynard Smith, Douglas Adams, Carl Sagan, and David Attenborough.

### Television Documentaries and Other Appearances

Dawkins has devoted much of his time and effort to the popularization of science. In addition to his numerous publications, this is well evidenced by his many appearances in television productions. In 1986, he released “Nice Guys Finish First,” a documentary in which he discusses selfishness and cooperation, arguing that the evolution favors the latter. In 1996, “Break the Science Barrier” was released, a documentary in which Dawkins promotes the perspective that scientific endeavor is not only useful but also intellectually stimulating and exciting. In 2004, Dawkins was interviewed in an episode of “The Atheism Tapes,” a BBC documentary series presented by Jonathan Miller. He discussed how he became an atheist and explained the fallacy of the “God of the gaps” argument, which uses gaps in scientific knowledge as evidence of God’s existence (Stanford Encyclopedia of Philosophy 2005). In 2005, Dawkins presented an episode of a British documentary series entitled “The Big Question.” This five-part series featured renowned scientists examining provocative questions about the universe and life. Dawkins’s episode answered the questions “Why are we here?” In 2006, “The Root of All Evil?” later retitled “The God Delusion” was released. Here, Dawkins argues that humanity would be better off without religion and belief in God. In “The Enemies of Reason,” a two-part documentary released in 2007, Dawkins aims to expose the “areas of belief that exist without scientific proof, yet manage to hold the nation under their spell” (National Secular Society 2007), such as the mediums, acupuncture, and psychokinesis.

In 2008, he wrote and presented a three-part television documentary “The Genius of Charles Darwin,” which won the “Best TV Documentary Series 2008” at the British Broadcast Awards. In “Faith School Menace?,” released in 2010, Dawkins exposes the effects of faith schools on both their students and the society. In 2012, “Sex, Death and the Meaning of Life” was released. In this three-part documentary, Dawkins explores the benefits that reason and science might offer in major events of human life, challenging the ideas about the soul, sin, and afterlife offered by religion. The same year, he starred in the second series of BBC’s “Beautiful Minds” documentary, which featured significant British scientists describing their big moments or discoveries. In the final episode of the season, Dawkins discussed “The Selfish Gene” and how this book made him a spokesman for atheism. In 2013, Dawkins starred in “The Unbelievers,” a documentary following him and Lawrence Krauss on their public lectures on the importance of science and reason in the modern world. He also gave two TED Talks, “Militant Atheism” (2002), and “Why the Universe Seems So Strange” (2005).

Dawkins has been featured in numerous television and radio programs, providing his political opinions and debating many religious figures. Additionally, he has made 70 appearances as himself in television shows and movies (Internet Movie Database 2017), such as “Doctor Who” – “The Stolen Earth” (2008) and “The Simpsons” – “Black Eyed, Please” (2013). He also appeared on The Colbert Report (2006) and The Late Late Show (2009).

Dawkins was featured as a narrator on the album of a Finnish symphonic metal band Nightwish, called “Endless Forms Most Beautiful,” which was released in 2015. He was a guest on two songs – “Shudder Before the Beautiful” and “The Greatest Show on Earth” (Richard Dawkins Foundation for Reason and Science 2015).

### Honors and Awards

During his career, Dawkins received many awards and honors. They include the Zoological Society

of London's Silver Medal (1989), the Finlay Innovation Award (1990), the Royal Society of London's Michael Faraday Award (1990), the Committee for Skeptical Inquiry's In Praise of Reason Award (1992), the Nakayama Prize for Achievement in Human Science (1994), the American Humanist Association's Humanist of the Year Award (1996), the International Cosmos Prize (1997), the Kistler Prize (2001), the Medal of Presidency of the Italian Republic (2001), the Freedom From Religion Foundation's Emperor Has No Clothes Award (2001, 2012), the Royal Philosophical Society of Glasgow's Bicentennial Kelvin Medal (2002), the Shakespeare Prize for Contribution to British Culture (2005), the Lewis Thomas Prize for Writing about Science (2006), the Galaxy British Book Award's Author of the year (2007), the Deschner Award (2007), and the Nierenberg Prize for Science in the Public Interest (2009).

### The Richard Dawkins Foundation for Reason and Science

In 2006, Dawkins founded a nonprofit organization called the "Richard Dawkins Foundation for Reason and Science" (RDFRS), with the mission to promote scientific literacy and a secular worldview and remove the influence of religion in science education and public policy (Richard Dawkins Foundation for Reason and Science 2017). Dawkins stated his belief that critical thinking is the real savior of humankind and that welcoming secular views in policy-making will "advance human safety, security, health, achievement, prosperity, and most of all, science" (Richard Dawkins Foundation for Reason and Science 2017).

In 2016, RDFRS merged with the "Center for Inquiry" (CFI), a nonprofit educational organization with a mission "to foster a secular society based on science, reason, freedom of inquiry, and humanist values" (Center for Inquiry 2017). Richard Dawkins is on the board of directors of this new, unified organization, and RDFRS continues to operate as its division.

## Richard Wrangham

Melissa Emery Thompson  
Department of Anthropology, University of New Mexico, Albuquerque, NM, USA

## Words

Richard Wrangham (born Leeds, Yorkshire, United Kingdom; 1948–) is a British primatologist and evolutionary anthropologist. He is an internationally renowned expert on wild chimpanzees who has made significant theoretical and empirical contributions across a wide range of

topics related to primate socioecology and human behavioral evolution. Wrangham has authored over 250 scientific articles and has written 3 books and co-edited 7 others. He married Dr. Elizabeth Ross in 1980 and has three adult sons.

Wrangham received his BA from Oxford University and subsequently received a PhD in Animal Behavior in 1975 from Cambridge University under the advisement of noted ethologist Robert Hinde. He received postdoctoral training from John Crook in the Bristol University Department of Psychology and from David Hamburg in the Stanford University Department of Psychiatry. Wrangham spent most of his early career at the University of Michigan, where he held a joint appointment in Biology and Anthropology. He joined the faculty of Biological Anthropology (now Human Evolutionary Biology) at Harvard University in 1989. He is currently the Ruth B. Moore Professor of Biological Anthropology. Wrangham received a prestigious MacArthur Foundation Fellowship in 1987 and was awarded the Rivers Medal from the Royal Anthropological Institute in 1993. He is a fellow in the American Academy of Arts and Sciences (1993) and the British Academy (2013) and received an honorary Doctor of Sciences degree from Oglethorpe University in 2011.

During his doctoral studies, Wrangham was one of the earliest students to conduct fieldwork on wild chimpanzees in collaboration with Jane Goodall at the Gombe Stream Research Center. His thesis, entitled “The Behavioural Ecology of Chimpanzees in Gombe National Park, Tanzania” focused on the chimpanzee diet and its influences on ranging and social behavior (Wrangham 1975). This work spurred a career-long emphasis on the fundamental role of nutrition and ecological variability in shaping the evolution and behavioral diversity of primates. In 1987, Wrangham established his own field site for the study of wild chimpanzees in Kibale National Park, Uganda. This study of the Kanyawara community, comprising 50–60 chimpanzees, is one of the longest-running naturalistic studies of wild primates and has yielded important scientific contributions on chimpanzee nutritional ecology, social

relationships, sexual and aggressive behaviors, hormone-behavior interactions, disease, culture, and communication.

In 1980, Wrangham published a seminal paper in primatology entitled, “An Ecological Model of Female-Bonded Primate Groups” (Wrangham 1980). Building on models of resource competition developed for birds and bats, Wrangham argues that the structure of primate groups depends primarily on female responses to the distribution of food resources in the environment. The common pattern of female-bonded social organization in primates results from the competitive advantages that females gain by forming cooperative alliances with other (mostly related) females to the exclusion of rivals. This contributed to a broader theoretical revolution in socioecology, coalescing in a volume Wrangham co-edited entitled, *Ecological Aspects of Social Evolution: Birds and Mammals* (Rubenstein and Wrangham 1986). While Wrangham’s original model has received numerous revisions and critiques, it remains an essential framework for understanding primate socioecology and has been a driving force behind inquiry into primate nutritional ecology. To this end, Wrangham directed a nutritional ecology laboratory at Harvard, partnering with Nancy Lou Conklin-Brittain to perform pioneering analyses of the nutritional composition of primate foods. Wrangham has

also published several influential papers on the use by primates of plants with medicinal properties and (with phytochemist Eloy Rodriguez) coined the term “zoopharmacognosy” to describe intentional use of such plants (Rodriguez and Wrangham 1993).

Wrangham has been a leader in the field of primatology for four decades. He co-edited *Primate Societies*, one of the first and most widely used textbooks in primatology (Smuts et al. 1987), along with an edited volume on chimpanzee behavioral biology: *Chimpanzee Cultures* (Wrangham et al. 1994). He served as president of the International Primatological Society from 2004 to 2008. Throughout his career, Wrangham’s work has been distinguished by an enduring focus on using primates to inform models of human evolution. In a 2000 article entitled “African Apes as Time Machines,” Wrangham joined paleoanthropologist David Pilbeam in laying out the argument for positioning chimpanzees (as opposed to gorillas or bonobos) as the most apt living model for the last common ancestor of *Homo* and *Pan* (Wrangham and Pilbeam 2000). Supported by nearly two decades of additional evidence, this argument forms the basis for a recent volume on *Chimpanzees and Human Evolution*, co-edited by Wrangham, Pilbeam, and Martin Muller (Muller et al. 2017). This text compiles evidence from diverse aspects

of hominid biology to probe the evolutionary roots of human traits.

In 1996, Wrangham published (with co-author Dale Peterson) the book, *Demonic Males: Apes and the Origins of Human Violence* (Wrangham and Peterson 1996). Once viewed as aberrant behaviors, infanticide, lethal intergroup raids, and sexual aggression have each proven to be habitual behaviors in one or more of human's great ape relatives. *Demonic Males* critically examines the functional significance of these behaviors within the apes, arguing for fundamental evolutionary continuities with violent behavior in human societies. Rather than merely portraying violence as biologically predisposed, Wrangham and Peterson emphasize its context dependence, using examples from humans and from the relatively peaceful bonobo to suggest ways to promote the better angels of our nature. Wrangham, in collaboration with Michael Wilson, Luke Glowacki, and others, authored numerous subsequent works examining empirical data on chimpanzee and human aggression and developing evolutionary models for collective violence in the contexts of gangs, warfare, and raiding in small-scale societies. He also co-edited, with Martin Muller, a volume using data on male-female aggression in humans, primates, and other mammals to position sexual coercion within the conceptual framework of sexual selection (*Sexual Coercion in Primates: An Evolutionary Perspective on Male Aggression Against Females*: Muller and Wrangham 2009).

In 1999, Wrangham collaborated with colleagues at Harvard University to propose a bold, new hypothesis that the innovation of cooking food would have fundamentally changed the course of human evolution. The paper "The Raw and the Stolen: Cooking and the Ecology of Human Origins" (Wrangham et al. 2000), later elaborated in Wrangham's book *Catching Fire* (Wrangham 2009), argues that a diet comprised primarily of cooked foods would not only have substantially increased energetic gains from foraging effort, resulting in the large body and brains and smaller dentition and digestive systems first observed in *Homo erectus*, but would have motivated changes in social behavior, including pair bonding, as a response to the increased demands

of defending stored foods. This has been one of the first significant challenges to the long-held model for meat-eating as the prime mover shifting hominid diets and lifestyles. With Rachel Carmody and others, Wrangham has generated numerous lines of metabolic, behavioral, and genetic evidence for the biological significance of cooking. This work has also stimulated renewed enthusiasm in the search for archaeological evidence for the control of fire.

In recent years, Wrangham has been instrumental in developing new theories for how evolutionary processes resembling domestication may have shaped behavioral diversity among hominids. Reduced aggressive behavior in bonobos compared with chimpanzees coincides with morphological and developmental differences that resemble the correlated changes that occur when species (e.g., dogs vs. wolves) have been artificially selected for reduced aggression (Hare et al. 2012). This suggests that selection against aggression may have been one of the major evolutionary forces promoting the divergence of chimpanzees and bonobos. Wrangham further argues that humans exhibit derived features that are suggestive of an analogous selection process. Such "self-domestication" to reduce reactive aggression may have been instrumental in the development of the complex, highly cooperative societies characteristic of our species. This argument will form the basis for Wrangham's forthcoming book, tentatively titled *The Virtue Paradox*.

Throughout his career, Wrangham has been an advocate for great ape conservation. In conjunction with his work in Kibale National Park, Wrangham initiated the Kibale Snare Removal Program in 1997 to reduce illegal poaching activities in the Park. The same year, he co-founded the Kasiisi Project with Elizabeth Ross to promote conservation via programs in the community that support education and health of children and families. Wrangham was also instrumental in partnering with the Uganda Wildlife Authority to develop the Kanyanchu chimpanzee ecotourism site in Kibale. In 2008, Wrangham and Ross co-edited *Science and Conservation in African Forests: The Benefits of Long-term Research*, which outlines strategies for creating synergy

between scientific research and conservation goals, citing tangible success stories from the teams working in and around Kibale National Park (Wrangham and Ross 2008). Wrangham is an ambassador for the Great Apes Survival Partnership (GRASP), an alliance between the United Nations and international government entities, conservation organizations, corporations, and scientists devoted to the protection of great apes. Wrangham also serves on the board of directors of the Pan African Sanctuary Alliance (PASA), a partnership among wildlife centers that coordinates the rescue and rehabilitation of primates impacted by habitat destruction and the pet and bushmeat trades. He is a member of the International Union of the Conservation of Nature (IUCN) Species Survival Commission Primate Specialist Group. He has previously served as a trustee or board member for several international conservation organizations, including the Jane Goodall Institute, Dian Fossey Gorilla Foundation, Wild Chimpanzee Foundation, WildAid, and the Great Ape World Heritage Species Project.

Wrangham has a rich academic lineage. Past PhD or postdoctoral advisees in faculty positions include Adam Clark Arcadi, Rachel Carmody, Colin Chapman, Richard Connor, Margaret Crofoot, Melissa Emery Thompson, Alexander Georgiev, Ian Gilby, Luke Glowacki, Tony Goldberg, Anne Goldizen, Brian Hare, Kevin Hunt, Dominic Johnson, James H. Jones, Cheryl Knott, Zarin Machanda, Andrew Marshall, Katie McAuliffe, Bethan Morgan, Martin Muller, Herman Pontzer, Lars Rodseth, Adrian Treves, Michael Wilson, and Brian Wood.

## Ritualization

Irena Petak  
Zagreb, Croatia

### Definition

Ritualization is a process by which non-signaling behavior patterns evolve to become communicative signals.

### Introduction

By signaling, an animal can influence the behavior of other animals and, consequently, change their own environment. Signals and displays are designed in the course of evolution for use in communication. They are shaped by natural selection to effectively convey information from the signaler to the recipient, i.e., to enhance the clarity of a signal and to reduce confusion (Endler 1993; Laidre and Johnstone 2013). The evolutionary process where activities, movements, and structures primarily not associated with communication obtained signaling function is called ritualization (Krebs and Davies 2006).

### History

The process of ritualization was first described by Edmund Selous in 1901 and later by Julian Huxley, who named it ritualization in 1914 (Dissanayake 2006; Lorenz 1966). Later it was used by Konrad Lorenz and other ethologists to describe ceremonial acts in social animals (Erikson 1966).

## Process of Ritualization

During evolution, signals may have derived from cues, incidental movements, or responses like those that can be seen during the motivational conflict (Krebs and Davies 2006; Laidre and Johnstone 2013). During the ritualization process, these behaviors become stereotyped, repetitive and conspicuous, or precise and gain the function of a signal to decrease misunderstanding (Krebs and Davies 2006; Hickman et al. 2008). The origins of signals can be found in different everyday activities, and some of them already are a source of information to other animals (McFarland 2006). The signal may incorporate some attractive or aversive cues, e.g., food or predatory cues (Pascoal et al. 2016).

Cues can provide information to others, although they are not evolutionarily shaped for the purpose of communication. They are conveying information unintentionally and passively, and they can be a by-product of some other animal activities (Biernaskie et al. 2018; Laidre and Johnstone 2013). On the other hand, signals are actively used in communication, and they are designed in the course of evolution to change the behavior of another individual. Usually, signals convey one information, and that can be the chemical, visual, auditory, tactile, seismic, or electric message. Similarly, displays are behaviors or series of behaviors that are highly stereotyped and used in communication to show specific physical characteristics (e.g., colors, patterns, and weapons) that are important for mate attraction, social (pair) bonding, coordination of group activities, intimidating rivals, predator deterring, etc. (Hickman et al. 2008; Laidre and Johnstone 2013; McFarland 2006).

If there is an evolutionary advantage, natural selection enhances the transformation of certain behaviors to become reliable and conspicuous signals. By the ritualization, signals become less ambiguous, easily distinguishable from some activities and other signals. From an evolutionary point of view, it is important to prevent hybridization, so different species need to have different signals that are used in courtship. Furthermore,

signal differentiation may play an important role in the prevention of aggression between related species that share habitat but differ in ecology (e.g., food). This is also important for the separation within species, such as between age groups or sexes, and consequently, interspecific signals were also under selection pressures that favored unambiguous recognition. Finally, some species signals may differ between individuals, giving possibility that individual animal is recognized by the other individuals in their social group, their mate, or by agonistic neighbors in territorial species. On the other hand, the process of ritualization is limited by signal-generating structures and sense organs available to a species, by habitat characteristics, the vulnerability of the species to predation, as well as some other factors (Cullen 1966).

Some locomotory movements, feeding behaviors, breathing, or body secretions can be ritualized to create new communication signals. Darwin was the first to point out that vocal signals may have originated from altered breathing patterns that were originally cues associated with the types of physical activity the breathing animal was preparing to undertake (Laidre and Johnstone 2013) and they are further developed by signaling environment (Endler 1993; Krebs and Davies 2006).

Ritualized behaviors have rigorously regulated speed and amplitude, so-called “typical intensity” (Morris 1957). They are also characterized by repetitions and invariable elements which are linked into a single obligatory sequence. By ritualization, motor patterns that are producing visual and auditory stimulation in communication channel become exaggerated, and those with mechanical function are reduced or even disappear (Dissanayake 2006; Lorenz 1966). Furthermore, behavior patterns become incomplete in execution, such as typical grooming which becomes restricted to certain parts of the body and movements become shortened (McFarland 2006). Therefore, by ritualization, new independent behaviors are developed, each with its own releasing mechanisms, spontaneity, and appetitive behavior (Lorenz 1966).

Behavioral changes are followed by morphological modifications that boost the

visibility and distinctiveness of the behavior, i.e., movements can be emphasized by skin, fur, or feather coloration (Wilson 1980). For example, in wild *Canidae*, the coloration of the coat is adjusted to enhance visual communication. Therefore, in wolves, coyotes, and red and gray foxes, the sides of the face or cheeks are white, and the lips are black. In that way, black lips and their horizontal retraction are enhanced, giving facial expressions that can be seen in fear or aggression (Fox 1971).

Finally, the motivation for some primary behavior may be different from the signal that evolved from it, for example, when female birds are begging for food during courtship ritual, even though they may not be hungry (McFarland 2006). However, some signals maintain the function of the behavior from which they developed. For example, threatening display may evolve through the ritualization of aggressive movements, i.e., real preparation for the fight, and the animal with clear signaling behavior could be preferred by evolution because it is disadvantageous to engage in actual fighting. Fights over mates, food, and territory may become ritualized to avoid bloody battles, in which even the winner can sustain dangerous injuries (Hickman et al. 2008; Wilson 1980).

Ritualization processes cannot be observed directly, but are instead researched by comparative studies of closely related species, wherein some species certain behaviors can be observed in their primary function while in other species, they become signals (Krebs and Davies 2006).

## Examples

Ritualization has been described in birds; mammals, including humans (Erikson 1966; Lorenz 1966); as well as fishes (Lorenz 1966) and invertebrates (e.g., marine *Crustacea*, Hazzlet 1972; caterpillar *Drepana arcuata*, Scott et al. 2010).

Bartoš et al. (2007) researched the agonistic behavior of fallow deer bucks (*Dama dama*) during the rut. Agonistic displays in deer are considered a ritualized behavior, where signals are obtained from a real fight, including the

display of vigor and strength. In this research, vocalizations and parallel walk increased the probability that one of the opponents will leave without an actual fight, while increased symmetry of the contestants' behavior was correlated with a higher likelihood of a fight. Therefore, fallow deer bucks efficiently use ritualized displays in the breeding season which minimizes the chance of injury that may be the consequence of real fighting.

Ground pecking of *Phasianidae* birds is another example of ritualization. To attract female a male domestic fowl (*Gallus*) and ring-necked pheasant (*Phasianus colchicus*) scratch the ground and peck food or pebbles – and this is the least ritualized form of display. In impeyan pheasant (*Lophophorus impejanus*) and peacock pheasant (*Polyplectron bicalcaratum*), the signal becomes more formalized and elaborated, so displays include slow rhythmical up and down movements of the head and tail (bobbing). Finally, male peacock (*Pavo*) starts with scratches and bows to attract a hen but then shows the tail spreading and pointing toward the ground with his beak (Dissanayake 2006; Krebs and Davies 2006).

Scott et al. (2010) show that a ritualized vibratory signal in caterpillars (anal scraping) originated from walking (locomotory behavior) and from physical fighting behaviors. In this way, competitors signal to each other to avoid the cost of fighting.

## Conclusion

Ritualization is one of the fastest evolutionary processes recognized in undomesticated animals (Lorenz 1966). This emphasizes the evolutionary flexibility of animal communication, as well as their importance in maintaining animal social life and reproduction.

## RNA

Richa Kumari

National Institute of Immunology, New Delhi, India

## Synonyms

Ribonucleic acid

## Definition

RNA is a single stranded nucleic acid which is a polymer of ribose sugar, phosphate group, and nitrogen bases (Adenine, Uracil, Guanine, and Cytosine). The main function of RNA is the regulation of gene expression and synthesis of cellular proteins, and it serves as a genetic material in some viruses.

## Introduction

Nucleic acids were first seen and isolated by Johann Friedrich Miescher in 1868, from the nucleus of the white blood cells who named them as nuclein. Later it was found that nucleic acids are also present in prokaryotic cells which are devoid of any nucleus. There are two types of nucleic acids present in the cell: DNA (Deoxyribonucleic acid) (Nucleotides and Nucleic Acid, UCLA) and RNA (Ribonucleic acid). Unlike DNA, RNA is single stranded nucleic acid which differs from the DNA in the presence of ribose sugar instead of deoxyribose sugar and uridine in place of thymidine. Moreover, RNA is less stable than DNA due to the

presence of an additional hydroxyl (–OH) group at the 2' position in the ribose sugar which can attack nucleophilically the phosphate group of next nucleotide making RNA highly reactive in alkaline conditions (Alberts et al. 2015; Watson et al. 2014). RNA can be grouped into two broad categories: genetic and nongenetic. In most plant viruses, some animal viruses and bacteriophage, RNA acts as genetic material. While the nongenetic RNA (mRNA, tRNA, and rRNA) are polymers of ribonucleotides, synthesized from the DNA. The main function of the nongenetic RNA is protein synthesis from the active genes (the process called as translation). Besides these two main categories some other forms of RNAs like snRNA (small nuclear RNA), snoRNA (small nucleolar RNA), miRNA (micro RNA), siRNA (small-interfering RNA), piRNA (piwi-interacting RNA), lncRNA (long noncoding RNA) also exist which serve primarily to regulate gene expression by binding to the complementary sequence on the mRNA. Sometimes RNA forms short-term double stranded helices by unusual non Watson-Crick pairing; G (Guanine): U (Uracil), this is because it can also act as an enzyme (Ribozyme) (Clancy 2008; Karp 2013). RNA also has a role in cell division, differentiation, and aging. Deregulation in the expression level and localization of RNA is associated with many human diseases like heart disease, Alzheimer's disease, cancer, etc (Cooper et al. 2009).

## Structure of RNA

Ribonucleic acid is a high molecular weight molecule which is a polymer of ribonucleotides. Each ribonucleotide unit is made up of D-ribose sugar (pentose sugar), a phosphate group, and a nitrogen base. Like DNA, RNA also consists of four types of nitrogen bases, the only difference being the replacement of thymine with uracil. These ribonucleotides in RNA are termed as adenylic, guanylic, cytidylic, and uridylic acids. Ribonucleotides are linked with phosphodiester bond in a polymer chain. Besides these four types of nitrogen bases RNA also has some methylated forms and pseudouridine. Generally RNAs are

single stranded molecules but can also occur in double stranded form as in reovirus, rotavirus, etc (Alberts et al. 2015; Watson et al. 2014) (Fig. 1).

## Types of RNA

RNA can be grouped as genetic and nongenetic RNA on the basis of the functions they perform (Berg et al. 2002; Watson et al. 2014)

- (A) Genetic RNA: In all plant viruses, some animal viruses (Influenza, Rous sarcoma) and bacteriophage (MS2) RNA is the genetic material, as DNA is absent in them. It can be either single or double stranded. The genetic RNA in viruses can self-replicate in a RNA-dependent RNA synthesis manner. The genetic RNA also codes for genetic information like mRNA for protein synthesis.
- (B) Nongenetic RNA: In the organisms where DNA carries the genetic information, RNAs constitute the nongenetic material. Nongenetic RNAs are synthesized as a complementary sequence on the DNA in the nucleus by the process called transcription and transferred to the cytoplasm to perform various cellular functions like protein

synthesis, gene expression, regulation, etc. Nongenetic RNAs are of three types which have specific functions in the process of protein synthesis:

1. Ribosomal RNA (rRNA): rRNAs are the structural part of the ribosome, which along with the ribosomal proteins constitutes around 80% of the total RNA. Ribosomes in the eukaryotic cells is 80s with 60s (large subunit) and 40s (small subunit). The large subunit is composed of three types of rRNAs viz. 28s RNA, 5.8s RNA, and 5s RNA, while the smaller subunit have 18s RNA. In prokaryotic cells, only three types of rRNAs are present, viz. 23s, 5s, and 16s. Except 5s all forms of rRNAs are synthesized by the RNA polymerase I in the nucleolar organizer region of the chromosome which is present inside the nucleolus.
2. Messenger RNA (mRNA): The term mRNA or information RNA was coined by the Jacob and Monad in 1961. mRNA is also termed as photocopy RNA as it carries the genetic information as a complementary sequence of DNA from the nucleus to the cytoplasm. It is synthesized in the nucleus by RNA polymerase II and

**RNA, Fig. 1** Structure of RNA. Ribonucleoside (D-ribose sugar + Nitrogen base) linked by phosphodiester bond

transported to the site of protein synthesis, i.e., ribosome. mRNA contains the genetic information in the form of triplet genetic code (codon) which are being translated into polypeptide chain on the ribosome. The primary transcript synthesized in the nucleus is termed as heterogeneous nuclear RNA (hnRNA), which further undergoes posttranscriptional modifications as 5' capping (addition of 7-methylguanosine), splicing (removal of noncoding intron and joining of coding exons), and polyadenylation (addition of poly A tail at the 3' end) to become functionally active and stable. Average life span of mRNA is 1–4 h. The mRNA is relatively less stable as it gets degraded by the cytoplasmic ribonuclease enzymes. Certain mRNAs with delayed translation are not released in naked forms but covered in a protein complex which is termed as informosome (Spirin 1979). Like rRNA, mRNA sometimes form loop or coiled structure by the base pairing between A: U and G: C.

3. tRNA: Soluble or transfer RNA is the smallest RNA among the three. It constitutes around 10–15% of the total RNAs and is synthesized by RNA polymerase III in the nucleus. They function as adaptor molecules for mRNA and amino acids during translation. A single tRNA carries a specific amino acid according to the codon on the mRNA to the site of protein synthesis. Each tRNA is specified by its 3' base anticodon to carry a particular amino acid. Alanine tRNA was first sequenced by Holley and colleagues in 1965 who also proposed the two-dimensional clover leaf model of tRNA structure. tRNAs are generally 70–80 nucleotides long containing five arms or regions viz. 3' acceptor arm (where amino acid attaches), D arm (recognize and aminoacylate tRNA), T $\psi$ C arm (possess recognition site for ribosome), anticodon arm (read and bind codon of mRNA), and variable arm (Fig. 2). Later Kim and Klug in 1974

**RNA, Fig. 2** Structure of tRNA with five arms as T $\psi$ C arm, D loop, anticodon arm, acceptor site for amino acid and a variable arm

gave the 3D model of tRNA which is L shaped. The tRNAs are relatively stable and transcribed continuously than the other types of RNA (Watson et al. 2014).

## RNA World Hypothesis

The RNA world hypothesis was proposed in 1960s independently by Carl Woese, Francis Crick, and Leslie Orgel. These three scientists first gave the idea that RNA can act as a catalyst. The “RNA world” phrase was first used by the Walter Gilbert in 1986. The RNA world hypothesis proposes that RNA is the precursor of all the existing forms of life (Watson et al. 2014). Before DNA and proteins came into existence, RNA was functioning both as a genetic material and as a biocatalyst/enzyme and in due course of evolution due to its instability and poor catalytic activity; it got replaced by DNA and proteins. In 1980s, two independent groups Thomas Cech and Sidney Altman discovered the catalytic activity of the RNAs and named them ribozymes, which provides strong supporting evidence of the RNA world hypothesis. 23s rRNA as a structural component in the larger subunit of ribosome have the catalytic activity for the peptide bond formation (peptidyl transferase). Similarly during RNA

processing, RNA component of the RNase is involved in the cleavage of the pre-mRNA and splicing (Higgs and Lehman 2015; Watson et al. 2014). Thus in the earlier life forms RNA was performing the enzymatic activity which was later taken over by proteins due to their increased stability and versatility.

## Conclusion

According to the central dogma theory by Francis Crick, DNA is duplicated into DNA by the process of replication; DNA is transcribed to synthesize RNA, which along with the ribosome synthesizes the proteins according to the coding information provided on the mRNA by the process of translation. The process of formation of DNA using RNA as a template by the RNA-dependent DNA polymerase is termed as reverse transcription and was discovered by Howard Temin and David Baltimore in 1970. Transcription occurs during the interphase of cell cycle. DNA transfers its genetic information as a complementary single stranded molecules, i.e., mRNA which along with other types of non-genetic RNAs (tRNA and rRNA) translate the information into specified polypeptide chain. The RNA world hypothesis explains that RNA evolved before DNA and proteins and was performing both the functions as genetic material as well as biocatalyst. Further research is needed to decode the RNA's involvement in various functions other than role in protein synthesis.

## Robert Hinde

Kelsey Moreno

University of Southern Mississippi, Hattiesburg, MS, USA

## Introduction

Robert Hinde was a British ethologist from the mid-twentieth to the early twenty-first century. He worked on a multitude of topics during his career, including bird migration, courtship in birds, mobbing behavior, social learning, parent-offspring relationships in primates, human social relationships, religion, morality, and war. He is well known for discounting Lorenz's drive model of behavior, developing a framework for animal social behavior, and campaigning for nuclear disarmament.

## Life and Work

Robert Hinde was born in Norwich in 1923, the youngest of four children, with one brother and two sisters. He was an avid naturalist from an early age, encouraged by his parents and an uncle. This passion for nature was nurtured while attending boarding school at Oundle, where he went on bird-watching expeditions with the headmaster and his son (Hinde 2010).

Following school, Robert joined the Air Ministry, serving as a pilot and navigator on Coastal Command. Kenneth Fisher, the headmaster of Oundle, arranged a closed exhibition (a scholarship based on personal recommendation) for Robert in St. John's College at Cambridge. This allowed him to leave the Air Ministry at the end of 1945, before the end of his original term of service, and start at Cambridge in January of 1946. Robert described himself at this time as working too hard and in a rush to get on with life (Hinde 2010).

Still an avid bird-watcher, Robert found the Cambridge sewage farm to be an excellent place for his hobby and visited about one to two times a week. Through the British trust for ornithology, he connected with bird-watchers across the country, a collaboration which led to several publications on the migrations of waders and terns (Hinde 2010). He also conducted an observational study on birds that had learned to open milk bottles, which was one of the earliest reports of observational learning in animals (Bateson 2017). Additionally, a chance spotting of a bird he did not recognize led to a consultation with local ornithologists, who excitedly determined it to be a moustached warbler, a rare bird that had not been recorded breeding in Britain. Recently, on a fifth review, the conclusion that this sighting was truly a moustached warbler was called into question (Hinde 2010); regardless, it was a major break in Robert's career.

One of the individuals who had consulted on the moustached warbler sighting was David Lack, who offered Robert a research assistant position following his graduation from Cambridge. Originally, Lack had intended to have Hinde work on the feeding habits of Jackdaws and Rooks as a test

of Gause's hypothesis, which is that two closely related species living in the same area don't compete (Hinde 2010). Robert, however, wanted to do behavioral research, and so with Lack's assistance, he began a naturalistic observational study of the behavior of great tits and closely related species, which became his graduate work at the University of Oxford. Incredibly, the population he began observing in 1948 has been studied every year since, providing a detailed long-term record on this model species in behavioral research. During Hinde's 2nd year as a graduate student, Niko Tinbergen, one of the developers of the field of ethology, joined the faculty at Oxford. Due to their similar research interests, Tinbergen effectively became a second mentor and taught Hinde how to analyze behavior, which was complementary to Lack's focus on using an ecological perspective (Hinde 2010).

In 1950, Bill Thorpe was in the process of establishing an ornithological field station in a four-acre field at Madingley. Thorpe was searching for a researcher to help develop and run the station; he knew Hinde from consulting on the moustached warbler sighting and so offered him the position (Hinde 1985). Together, they and the researchers and students they brought in developed the site and studied a variety of aspects of bird behavior. Robert particularly appreciated that he was able to do whatever research he wanted there (Hinde 2010).

His early research at Madingley focused on courtship and conflict in birds, particularly finches. For his courtship studies, he used hybrid birds to parse genetic and environmental influences on courtship postures between finch species. Furthermore, he found links between the social environment, hormones, and behavior patterns. His other main study with finches was an effort to use the mobbing responses of chaffinches to large predators, such as owls, to measure the action-specific energy reservoirs and releasing stimuli thresholds integral to Lorenz's model of motivation. However, in attempting to do this, he found that the model's components were not fixed and thus could not be measured. This led him to the conclusion that this drive model was not useful as it is too vague and lacks unitary definitions and

mechanisms. Instead, he argued that our ability to analyze chains of behavior patterns makes the concept of drive unnecessary, a stance which did not endear him to Konrad Lorenz. Additionally, this work demonstrated habituation of chaffinches to owls, indicating learning was taking place (Klopfer 1974; Hinde 2010).

Around the same time, Hinde was also assisting Thorpe with his research on imprinting. Thorpe was particularly interested in understanding the roles of instinct and learning for birdsong. Robert described his mentor as ahead of his time, for he heavily favored cognitive explanations which were not yet widely accepted (Hinde 2010). This research also sparked an interest in studying the parent-offspring relationship, which would prove to be the foundation of Robert's next research direction.

Furthering the development of Robert's new interest in parent-offspring relationships was John Bowlby's invitation to his weekly seminar on child development. Bowlby was a psychoanalyst interested in the early relationships of mothers and children and the impact of separation events on that relationship and later behavior. His seminar brought together scientists from a range of perspectives to weigh in on this topic; meetings typically included Bowlby, a Freudian, a Kleinian, a Piagetian, a Hullian leaning theorist, a Skinnerian, an anti-psychiatrist, two to three psychiatric social workers, and Hinde as an animal ethologist (Hinde 1985).

Additionally, Bowlby wanted to find experimental evidence of the negative impact of separation events and so worked with Hinde to set up a rhesus monkey colony, as they were one of the few nonhuman primates for which any knowledge existed at the time. To test the impacts of separation on parent-offspring bonds, they constructed housing had six large pens with inside areas for each, all connected to a large central area, with each large pen eventually housing a group of one male and three or four females with dependent offspring. This allowed control of the features of separations to mimic different hospitalization scenarios. Astonishingly, separations of just 10 days had long-term negative effects, results which helped change hospital regulations

to minimize patient separation from their families (Hinde 2010).

With the establishment of the monkey colony in the early 1960s, the Ornithological Field Station at Madingley became the sub-department of animal behavior. Additionally, Hinde was awarded a Royal Society Research Professorship in 1963, a very prestigious position which ensured job security and allowed him to focus on research and mentorship. The addition of primates to Madingley led to Robert becoming the mentor for students focusing on primate behavior, notably Jane Goodall and Dian Fossey, who worked with chimpanzees and gorillas, respectively (Bateson 2017; Hinde 2010). Both women had started in their research through Louis Leakey and needed a formal Ph.D. advisor. Notable students of Robert came to include Richard Wrangham, Tim Clutton-Brock, Dorothy Seyfarth, Phyllis Lee, Joyce Poole, and Judy Dunn. Robert felt that his role as supervisor was to teach his students to think critically and record behavior systematically. He also maintained that research students learn more from each other than their supervisor, and the supervisor learns at least as much from his or her students as the students do from the supervisor. For example, Jane and Dian both influenced his research by demonstrating the importance of individual differences in animals (Hinde 2010).

Robert's work with primates led, in the early 1970s, to an interest in the nature and dynamics of human social relationships, an interest he shared with his second wife, Joan. Together, they brought ethological methods to studies on children in pre-schools and in the home. Along with Robert's postdocs, they also conducted a cross-cultural comparison of family relationships between Britain and Hungary. Joan later became a leader in attachment theory (Hinde 2010).

As he became more active in studying interpersonal relationships in animals and humans, Robert noticed there was little research on the level which lies between group behavior and brief interactions. Thus, he set about describing what would be needed to study long-term dyadic relationships and developed a framework for understanding the connections between different levels of social behavior (interactions,

relationships, and social structure) which is widely used today. The model's greatest contributions were describing how each level is built from the content, quality, and patterning of the level below it, resulting in different properties for each (Hinde 1976).

Robert Hinde officially retired in 1989, though he remained academically active until his passing in 2016 (Anderson 2017). Upon his official retirement, he became headmaster of St. John's College, where he helmed the building of a new library. His academic focus shifted to matters of war, morality, and religion. He wrote multiple books on the topics, including *Defended to Death*, *Why Gods Persist*, and *Why Good is Good*. His books on religion examine the universal elements of religious belief, as well as how each is tied to human nature and how religion likely came about. While Hinde himself was atheist, he strongly believed that we have no right to take away the comfort of religion from someone else, especially if we have nothing to offer in its place. In order to have an acceptable alternative, he felt we should develop an outline of how to have morality without religion. His stance on war was that it is a stupid way of solving disputes and extracts vast amounts of resources which could be put to much better use. He was influenced by his own experiences in the military, his brother's death in WWII, and his research on behavior. This strong conviction motivated his active involvement in multiple anti-war organizations, including the Ex-servicemen Campaign for Nuclear Disarmament, the Movement for the Abolition of War, and the British Pugwash Group, for which he served as chairman for several years in the 2000s (Anderson 2017; Hinde 2010).

Throughout his life, Robert aimed to make the world a better place, a guiding principle which influenced him from his early work with birds to his later work against war. He made many contributions to science and society and was particularly influential in promoting cross-disciplinary perspectives. He recognized ethology's strengths and greatest achievements were in its links to other disciplines and played a

key role in integrating its principles and techniques with many other fields, including comparative psychology, physiology, learning, and many other biological and social science perspectives (Hinde 1982, 2010). He was also instrumental in moving ethology away from Lorenz's model building and instead promoted understanding behavior in a manner compatible with physiological processes. In a 2010 interview, he said that he was very lucky in his life in many ways, from the places he worked to the timing of his career, which enabled him to follow his interests wherever they led and work in new, exciting fields.

## Robert Mearns Yerkes

Tiffany A. Baker

University of Southern Mississippi, Hattiesburg,  
MS, USA

Robert Mearns Yerkes (May 26, 1876 – February 3, 1956) was an American comparative psychologist best known for initiating the intelligence testing movement and establishing the first American primate laboratory. His namesake, the Yerkes National Primate Research Center, is now located at Emory University in Atlanta, Georgia. The Yerkes-Dodson Law that describes the parabola-shaped relationship between performance and arousal is well known and used in a multitude of disciplines (Hilgard 1965).

Growing up on a rural farm in Bucks County, Pennsylvania, Robert M. Yerkes, in his 1930 autobiography, recalled a happy childhood that inspired curiosity and allowed for a young scientist's mind to flourish. In his early years, however, Robert and his eldest sister both contracted scarlet fever. She passed away but Robert survived (Yerkes 1930) although he was plagued with chronic fatigue for many years following (Hilgard 1965). He had three other siblings, all quite a bit younger than Robert. Although Robert Yerkes' mother and father never attended college, he had an uncle and cousin who practiced medicine. They encouraged the young Yerkes to study medicine in order to attain an education that would provide an easier lifestyle, a doctor's lifestyle, rather than the difficult and labor-intensive livelihood of his father, a farmer (Yerkes 1930).

At the age of sixteen, Yerkes' uncle, Dr. Edward Atkinson Krusen, provided him room and board along with a small compensation for schooling at Ursinus College in exchange for household chores. Five years later, in 1892, he graduated with an Atrium Baccalaures (A.B.) degree, or more commonly known as a Bachelor of Arts. Yerkes was then offered a one-thousand-dollar loan from Harvard University to pursue graduate work in zoology. Needing the money,

Yerkes abandoned medicine and began as a provisional undergraduate for 1 year beginning in 1897. Yerkes proved worthy of graduate status and gained another A.B. degree along the way. His first paper, *Reaction of Entomostraca to Stimulation by Light* (Yerkes 1899), was published under the supervision of Charles B. Davenport in the Laboratory of Comparative Zoology in 1899 at Harvard University (Yerkes 1930).

It was Josiah Royce, an American philosopher, who suggested comparative psychology to Yerkes that began his study of animal behavior and cognition and how it relates to that of different animals or humans, thus pairing his main interests, zoology and psychology. Hugo Münsterberg, shortly thereafter, extended a position to Yerkes in his laboratory to study comparative psychology and subsequently became a mentor and dear friend. Over the course of his graduate career, Yerkes lectured in courses on genetic and comparative psychology as well as conducted what he referred to as psychobiological research. His dissertation, *The Psychic Process of the Frog* that examined learning in the frog while in a labyrinth, was completed in 1902 for which he earned a Doctorate of Philosophy in Psychology from Harvard University (Yerkes 1930).

Yerkes' research interests first included various aspects of organic receptivity and its relation to behavior. Using subjects such as amphibians and reptiles, he frequently published on these topics between 1905 and 1912 (Dewsbury 1996). He was also dedicated to the advancement of comparative psychobiological methods and, therefore, devoted much of his research and time to the development of tasks that could reliably measure phenomenon across different species (Yerkes 1930). Soon his subject choice evolved from amphibians and reptiles to lower mammals. *The Dancing Mouse* (1907), his first book, helped establish the use of mice and rats as standard laboratory subjects in psychological testing (Dewsbury 1996). His goal ultimately became to establish a comparative psychobiological research center that would house anthropoid subjects (Yerkes 1930).

After graduation, Yerkes attained a position at Harvard and remained there for the next 15 years (1902–1917). As an instructor and later as assistant professor of comparative psychology, his colleagues included eminent scholars such as William James, Hugo Münsterberg, Francis Peabody, George Santayana, Dickinson Miller, Robert MacDougall, Edwin B. Holt, Ralph B. Perry, and John D. Dodson (Yerkes 1930). In 1908, Yerkes and Dodson formulated the famous Yerkes-Dodson Law describing the parabola-shaped relationship between arousal and performance (Dewsbury 1996).

With Yerkes marriage to biologist Ada Waterson in 1909, his home and professional life flourished as she participated with him in numerous research projects and cowrote one of his classics (Yerkes 1930), *The Great Apes: A Study of Anthropoid Life* (Yerkes and Yerkes 1929).

Although Yerkes studied observable phenomenon, he believed psychologists should also study mental processes (Hilgard 1965). He thought it was possible to empirically investigate the phenomena of experience in relation to the environment in which it occurred. Therefore, he rejected John B. Watson's radical behaviorism, but as a participant in the developmental phase of the theory with Watson, he found merit in parts of behavior theories (Yerkes 1930). Records of correspondence between the two provide evidence of close collaboration and sharing of ideas (Hilgard 1965). Watson and Yerkes, through their collaborations, also contributed to the improvement and standardization of methods for the comparative study of vision (Yerkes 1930).

Edward B. Titchener, a British psychologist who worked with Wilhelm Wundt, often exchanged letters with Yerkes in which they discussed the psychology of the self. Yerkes was intrigued with the use and measurement of introspection and wrote his first and only textbook, *An Introduction to Psychology* (1911), to explore the topic thoroughly and gain a clearer conceptual understanding of introspection and the psychology of the self (Yerkes 1930). Furthermore, Yerkes was responsible for the first American scientific journal devoted to the study of animal

behavior in 1911, the *Journal of Animal Behavior* (Burkhardt 1987).

Beginning in 1913, Yerkes became a hospital psychologist at Boston Psychopathic Hospital while continuing his Harvard obligations. During the next 5 years at the hospital, he discovered a need for improved techniques and measurement regarding psychobiological issues. In 1915, Yerkes helped to create the Yerkes-Bridges Point Scale of Intelligence which measured aspects of intellectual activity and the multiple-choice method for the study of ideational behavior (Yerkes 1930).

In 1917, The University of Minnesota asked Yerkes to reorganize the psychology department and establish a new laboratory. After much consideration, Yerkes reluctantly accepted the position and left Harvard and the Boston Psychopathic Hospital in the spring of 1917 for Minnesota. Yerkes did manage to set the proper motions in place for the psychology department and secure a location for a new laboratory, but his stay at Minnesota was cut short with America's entry into the First World War (Yerkes 1930).

One year prior, in 1916, Yerkes had become president of the American Psychological Association (APA), Psychology's flagship organization. As such, he found himself at the forefront of Psychology when America entered World War I in April of 1917. A group of psychologists, including Yerkes, happened to be at Harvard the time. They felt compelled to aid in the war efforts and recognized an application of Psychology was needed (Yerkes 1930). Thus, the intelligence testing movement began, and the Army Alpha and Beta tests were born out of the Committee on the Psychological Examination of Recruits that Yerkes chaired. The Army Alpha test allowed matching of recruits to skills required by appropriate positions in the army. The Beta test served the same function but was administered to foreigners and those who were illiterate. As president of APA, Yerkes' role was to take the initiative in organizing the testing effort. He established the appropriate relations with the Medical Department of the Army despite several obstacles and, through this arm of service, became personally responsible for the psychological examination of

recruits. For the first time, intelligence tests were administered to a group of people instead of individually allowing 1,726,000 United States soldiers to be tested during the movement (Hilgard 1965).

Psychology received positive public acknowledgment for the success of the intelligence testing movement allowing Yerkes and other psychologists to begin testing the general population with ease. The tests used have been called the forerunners of standardized tests such as the scholastic aptitude test (SAT), which measures college readiness. Yerkes also published two books that continue to serve as models for the advancement of intelligence testing, *Army Mental Tests* (1920) and *Psychological Examining in the US Army* (1921) (Hilgard 1965).

The intelligence-testing movement also demonstrated Psychology's usefulness as a profession. Given Yerkes' vital role, he is often credited for aiding in the application of psychology in a professional capacity (Hilgard 1965). This is important because the role of American psychologists at the time was to conduct research exclusively.

Psychology accumulated massive accumulation of data after the completion of the first mass-scale-testing movement. Yerkes's personal analyses led him to controversial conclusions about the origins of racial and ethnic differences in intelligence that coincided with the eugenics movement in the US and abroad. Along with racial and ethnic differences, he also found generational differences in IQ which led him to conclude that IQ was declining in the US. His interpretation of the findings about race and ethnicity resulted in more restrictive immigration laws. Eventually, his conclusions were refuted, but the data remain a psychometrist's treasure trove (Hilgard 1965).

Shortly after the 1918 Armistice, Yerkes had to choose between continuing his work with mental testing to aid the war efforts or following his academic pursuits and returning to the position at the University of Minnesota that was interrupted by the war. He ultimately decided to abandon his post at Minnesota to complete a large report of Psychology's effort during the war and to

begin securing financial support for the systematic study of anthropoid apes (Yerkes 1930).

Yerkes joined the faculty at Yale University in 1924 where he remained for the next 20 years. He began pursuing his initial goals of opening a primate facility and renewed his investigations of the great apes. He soon was the top researcher in the field. Previously, he had published a plan of action to open a primate facility (Yerkes 1916), but the proposal lacked financial support. His professorship at Yale provided him with the time necessary to acquire the finances and complete his plan. In the summer of 1924, he traveled to Havana, Cuba to observe a large colony of primates (Yerkes 1930). Upon returning, he moved to New Haven, Florida and purchased two chimpanzees, Chim and Panzee, from a zoo. He brought the two chimps home, where they lived in a bedroom and were taught to behave much like small, human children. Yerkes documented this experience in his paper *Almost Human* (Yerkes 1925; Hilgard 1965).

In 1929, he reached his long-time goal and established the Yale Laboratories of Primate Biology in Orange Park, Florida. It was the first center for the study of the neural and physiological bases of behavior and the first primate laboratory of comparative psychology (Yerkes 1930). After Yerkes resignation as director in 1941, the center was renamed Yerkes Laboratories of Primate Biology. Ninety chimpanzees were studied under his direction. Yerkes' publication, *Chimpanzees: A Laboratory Colony* (1943), established the significance of studying primate behavior to gain understanding about human behavior and was his last work. Yerkes retired from Yale University in 1944 (Hilgard 1965).

After retirement, Yerkes continued to serve as chairman of the National Research Council Committee for Research on Problems of Sex (1921–1947). During this time, he was fundamental in the sponsorship of projects that led to such studies as the Kinsey report which focused on human sexual behavior (Hilgard 1965).

On February 3, 1956, at age 79, Yerkes passed away in New Haven, Connecticut, from coronary thrombosis after spending 2 years as an invalid (Hilgard 1965). Near Yale University, he is buried

in Evergreen Cemetery in New Haven, Connecticut, with his wife who died in 1965. After his death, the Yerkes National Primate Research Center was relocated to Atlanta, Georgia, at Emory University where anthropoid subjects are still studied today (Hilgard 1965).

<sup>2</sup>The Ohio State University – Mansfield, Mansfield, OH, USA

<sup>3</sup>Department of Biology, Kalamazoo College, Kalamazoo, MI, USA

## Introduction

Based on their novel combination of mechanistic and functional questions in a natural setting, Robert Seyfarth and collaborator Dorothy Cheney inspired cross-disciplinary scholars of animal behavior for decades. Seyfarth and Cheney are not only pioneers in ASKING questions about the social lives and minds of animals, they also revolutionized the methods we use to investigate these questions.

## Background

Robert M. Seyfarth was born February 16, 1948, in Illinois to Robert and Mary (Moo) Seyfarth. After graduating from Exeter in 1966 (leaving behind a promising cheerleading career), Seyfarth received his Bachelor's degree in Biological Anthropology from Harvard in 1970, earned his PhD in Animal Behaviour from Cambridge in 1976, and completed a postdoctoral position at Rockefeller University in 1979. After tenure-track positions at Rockefeller University and UCLA, he joined the Department of Psychology at the University of Pennsylvania in 1985 until his retirement in 2016. Seyfarth is an elected fellow of the American Psychological Association (Division: 3 1996; Division 6: 2002), Animal Behavior Society (1997), Association for Psychological Science (2007), and American Academy of Arts & Sciences (2012). Seyfarth holds an honorary PhD from University of Neuchâtel, Switzerland (2013), received the Distinguished Primatologist Award from the American Society of Primatologists (2016), and was elected into the US National Academy of Sciences (2017).

Seyfarth married Dorothy L. Cheney in 1971, having two children, Caroline (Keena) and Lucia (Lucy). Seyfarth and Cheney conducted joint field research together throughout their careers (frequently joined by their daughters), focusing on communication, cognition, and social behavior of wild monkeys. Their award-winning book *How Monkeys See the World: Inside the Mind of Another Species* (Cheney and Seyfarth 1990a) is an engaging summary of their 11 years spent studying vervet monkeys in Amboseli National Park, Kenya. Their second book *Baboon Metaphysics: The Evolution of a Social Mind* (Cheney and Seyfarth 2007) describes their 16 years of research on baboons in the Okavango Delta of Botswana. Counted among its many accolades, *Baboon Metaphysics* was runner up in the *Diagram Prize for Oddest Book Title of the Year* (narrowly losing to *The 2009–2014 World Outlook for 60-milligram Containers of Fromage Frais*, but soundly beating *Curbside Consultation of the Colon*). Through both hard-hitting science and a clever writing style, Seyfarth and Cheney develop an argument in both their books for the adaptive value of social cognition. They encourage the reader to look behind the curtain to explore the many surprising ways that animals are similar to ourselves and, perhaps more importantly, where they fall short in their cognitive and communication abilities.

Seyfarth and Cheney have published over 200 articles, commentaries, and book chapters – 90% of these written together – on their original empirical work (many alongside colleagues and students) or that review the implications of such work. Their major contributions are in vocal communication and social cognition. We summarize the former here, but to understand Seyfarth's impact on the field of social cognition see “► [Dorothy Cheney](#)” entry in this series. Harrowing tales of encounters with hippos, lions, and other assorted megafauna are best communicated by Seyfarth and Cheney themselves.

## Contributions to Social Behavior and Communication

Under the guidance of their dissertation advisor, the eminent ethologist Robert Hinde, Seyfarth,

and Cheney were among the first major wave of primatologists that focused on social behaviors and relationships from the standpoint of the individual. For example, Seyfarth wrote a seminal paper (1977) demonstrating that simple, individual-level rules could predictably produce the grooming networks seen in various different primate social systems. Given their interest in the adaptive value of social bonds (see “► [Dorothy Cheney](#)” entry), grooming remains an important measure of affiliation in Seyfarth and Cheney's long-term research.

After completing dissertations on the social behavior of chacma baboons in Mt. Zebra National Park, South Africa, Seyfarth and Cheney began a long-term study of vervet monkeys in Kenya. The impetus for this project was their postdoctoral collaboration with Peter Marler, an ethologist well known for his groundbreaking work on bird song learning and for his interdisciplinary, big-picture ideas. Public notoriety for this research program was launched with a now famous publication in *Science* (Seyfarth et al. 1980). In it, Seyfarth and colleagues confirmed a previous finding, by Thomas Struhsaker, that leopards, raptors, and snakes elicited distinct calls from the monkeys as well as predator-specific escape responses from listeners. However, it remained unclear if the jarring nature of the loud alarm calls simply alerted the monkeys, who then gathered information by looking at the caller or by spotting the predators themselves. To determine if, from the listener's point of view, the three alarm calls mean roughly “there is a leopard in that bush,” “there is a raptor diving at my head,” or “there is a poisonous snake-like object crawling between my legs,” Seyfarth and colleagues adopted methods from wild bird vocal studies – playback experiments. In 88 carefully designed trials, they played examples of each call type from a hidden speaker to unsuspecting subjects. Seyfarth and colleagues found that based on acoustic features alone, alarm calls produced the appropriate, predator-specific escape response in listeners; for example, subjects ran up trees following the sound of leopard calls, dove into bushes following the sound of raptor calls, or stood and looked into tall grass following snake calls. Thus, alarm calls functioned as

though they were semantic to the listener; the call seemed to signify objects or events external to the signaler, much like words function in human language.

This experiment inspired decades of research into the potential semantic properties of non-human primate vocalizations and ushered in an era of playback experiments in primatology. Although such experiments had been conducted on birds, amphibians, and insects prior to 1980, the method had only crossed into primatology a few times. Rather than using the age-old approach of simple observation to study primates, playbacks added a level of rigor and control not previously available. However, the logistics of conducting these experiments with social mammals was far more complicated than with frogs or birds. Seyfarth and Cheney have continually conceived new ways to incorporate this technique in a systematic way, creating a tool that is now a mainstay in behavioral ecology.

Seyfarth and Cheney's future studies would occasionally revisit alarm calls and predation, finding that listeners can glean information about predators from a variety of dissimilar sounding calls (e.g., Diana monkeys: Zuberbühler et al. 1999), and that listeners can differentiate alarm from nonalarm calls even when the call types grade together along an acoustic continuum (e.g., baboons: Fischer et al. 2001). However, the emphasis of their future work combined playbacks with their first interest – social relationships. With this new tool, they could not only ask about the functional significance of a call during dyadic interactions, they could also use it to ask their subjects, in the animal's own tongue, "*What do they know – and do they know they know it?*" (Cheney and Seyfarth 1990b, p. 38).

To probe the minds of monkeys, Seyfarth and Cheney used unremarkable vocalizations to provide remarkable insight. Their study of grunt vocalizations, first with vervets and later with chacma baboons in Botswana, is a perfect illustration of this elegant approach. Grunts are ubiquitous primate vocalizations, produced by many species, and the most commonly uttered calls of vervets and baboons. Seyfarth and Cheney found that vervets utter four acoustically distinct grunts

in four different social situations and that subjects in playback experiments responded appropriately based on acoustics alone (Cheney and Seyfarth 1982). Whereas they also found that baboons have at least two acoustically different types of grunts and respond appropriately to these calls during playback experiments (Rendall et al. 1999), baboons also appear to consider context. Grunts appear to mediate social interactions, mollifying subordinate animals and facilitating reconciliation after aggression. For example, female baboons are more likely to have an affiliative interaction (e.g., groom) if a dominant individual grunts either following an aggressive encounter with or an approach of a subordinate female. However, grunt exchanges do not simply correlate with social bonds. For example, mothers and daughters are much less likely to grunt at each other during an approach than other dyads, and high-ranking animals are more likely to grunt at low-ranking than the reverse, suggesting these calls signal benign intent (Silk et al. 2016).

Using the same model, Seyfarth, Cheney, and colleagues have uncovered the function of other vocalizations. For example, the loud wahoo vocalizations of male chacma baboons are given in several contexts and although these calls intergrade – making it difficult for human observers to differentiate them in the field – female baboons respond differently to “alarm” wahoos (produced when encountering predators) than “contest” wahoos (given during male-male competitive displays). Using behavioral observations and acoustic analysis, Seyfarth and colleagues determined that contest wahoos and the displays that accompany them are honest indicators of male condition, and during playback experiments, subjects were more attentive to exaggerated calls that simulated a superior opponent. In another experiment that simulated male-male contests, subjects were more interested in anomalous interactions between males of disparate ranks – which typically indicate a major resource is being disputed – but only when the subject outranked both callers (Kitchen et al. 2013 and citations therein). This experiment demonstrated that males were assessing not just call meaning but also caller identities and their own relative rank.

Using playbacks of various vocalizations to simulate social situations, Seyfarth, Cheney, and colleagues have also uncovered details about the social lives of these animals. For example, lactating female baboons form “friendships” with some resident males – dyadic relationships that are quantifiably distinguishable from others based on frequency of affiliative behaviors (approaches, infant handling, grooming). Using playback experiments to simulate attacks on females in various scenarios, Palombit et al. (1997) demonstrated that these friendships actually serve to protect small infants, likely the male’s offspring, from infanticide by immigrant males.

In another experimental set-up designed to mimic a social interaction, Seyfarth and colleagues found that both vervet and baboon females were more likely to attend to another female’s threat grunts (a vocalizations used to solicit aid) if the dyad had recently shared a grooming bout (Cheney et al. 2010 and references therein). This is empirical evidence that grooming vs. cooperation during aggressive interactions are different “currencies” reciprocally exchanged among nonkin in a social group. Despite experimental tests on several species, researchers have only rarely demonstrated reciprocal altruism/contingent cooperation in the lab. Thus, Seyfarth and Cheney’s work suggests that, by providing both external and internal validity, experimental studies in the wild are the most useful for uncovering “emotional bookkeeping” in socially complex species (Cheney et al. 2010).

## Conclusion

Using innovative field techniques (and consummate parlor game skills), Seyfarth, Cheney, and their various collaborators have dispelled many of the false dichotomies traditionally believed to separate primate vocalizations from human speech (Seyfarth and Cheney 2017). For example, they clarified that although nonhuman primates have intergraded vocalizations, conspecific listeners can parse these calls as though they are discrete (e.g., Fischer et al. 2001). They

demonstrated that alarm call production is innate in young vervet monkeys, but they learn over time which stimuli should elicit calling (e.g., producing raptor alarm calls to eagles, not to falling leaves) and how to appropriately respond to the alarm calls of others without needing visual cues (Seyfarth et al. 1980). Thus, restrictions in production are not necessarily limitations in usage and comprehension. Finally, they have shown that meaning and emotion are not mutually exclusive ends of a vocal spectrum – rather, nonhuman primates can actively respond to vocalizations based on call meaning, caller identity, their own identity, and context.

By breaking down these false dichotomies, Seyfarth and Cheney not only uncover the ways we are similar, they also focus our attention on what is truly different between human speech and nonhuman vocalizations – namely, intentionality and theory of mind. However, they point out that the social mind of the monkey can interpret combinations of signals in a variety of sensory modalities, holds representational information on social interactions, and can contend with multiple discrete categories simultaneously in a hierarchically structured, rule-governed, and open-ended fashion (Seyfarth et al. 2005). In their words, “*Baboons – like dogs, chimpanzees, and many other species – understand much more than they can say. Their language of thought is impressive; their ability to articulate their thoughts much less so.*” (Cheney and Seyfarth 2007, p. 276). Despite limitations in vocal communication, they hypothesize that the ability of nonhuman primates to grapple with social knowledge provides a lattice-work on which human language could have been built (Seyfarth and Cheney 2017).

## Robert Trivers

Gavin Vance<sup>1</sup> and Todd K. Shackelford<sup>2</sup>

<sup>1</sup>Oakland University, Rochester, MI, USA

<sup>2</sup>Department of Psychology, Oakland University, Rochester, MI, USA

Robert Trivers is an American evolutionary biologist who has made a number of significant contributions to evolutionary theory, including parental investment theory and parent-offspring conflict.

## Parental Investment Theory

Parental investment theory was developed by Trivers (1972) and predicts that, in sexually reproducing species, the sex that invests more resources in its offspring will also be more selective when choosing a mating partner. As a result, the sex that invests less parental resources will experience greater intrasexual competition for mating partners and will exert greater mating effort to gain sexual access. Differences in minimum obligatory parental investment have also informed predictions regarding sex differences in sexual strategies. For example, women rate financial resources as more important in a potential mate than do men (Buss 1989) and are less interested in casual sex than are men (Buss and Schmitt 1993). Parental investment theory has led to numerous hypotheses regarding animal behavior and cognition as it relates to offspring investment and mating strategies.

## Parent-Offspring Conflict

Parent-offspring conflict (Trivers 1974) refers to the differing levels of desired investment from the perspectives of a parent and his or her offspring. Although parents may increase their genetic success by investing resources in offsprings to a certain extent, there is a point at which the costs of offspring investment outweigh the potential benefits to the

parent. For example, a parent who invests too heavily in a single child may reduce the likelihood of their own survival and, as a result, the likelihood that they will produce more children. Additionally, a parent with two or more offspring may maximize their reproductive success by investing equally in each offspring or by investing more heavily in the offspring with better prospects for survival and reproduction. However, from an offspring's perspective, they can maximize their reproductive success by extracting as many parental resources as possible, regardless of what the parent desires to invest. Further, because any individual shares 100% of its genes with itself and approximately 50% of its genes with a full sibling, an offspring may attempt to extract a disproportionate amount of investment from their parent, thereby increasing his or her survival or reproduction but to the detriment of siblings.

## Reciprocal Altruism

Reciprocal altruism (Trivers 1971) refers to any behavior performed by an organism that temporarily reduces its own genetic success but increases the genetic success of another organism. Kin altruism proposes that, by engaging in behavior that increases the fitness of a genetic relative, even at the temporary expense of one's own fitness, an organism may enhance its overall genetic success by promoting the success of shared genes in another organism (Hamilton 1964). Reciprocal altruism, in contrast, suggests that an organism may improve its own fitness in the long-term by incurring a temporary cost to help a genetically unrelated organism, who may return the favor at some point in the future. Altruistic behavior may also generate long-term benefits for an individual by improving social reputation with fellow group members.

## Trivers-Willard Hypothesis (Facultative Sex Ratio Determination)

The Trivers-Willard hypothesis (Trivers and Willard 1973) suggests that female mammals

may alter the sex ratio of their offspring in response to environmental cues. The hypothesis suggests that, although selective pressures often promote the production of an equal sex ratio among offspring, environmental pressures may facilitate the reproduction of one sex more than the other. For sexually reproducing species in which males compete with for sexual access to females, parents will invest in sons when environmental conditions are more favorable and daughters when conditions are less favorable. Because males have lower obligate parental investment than females, they also have the potential to sire more offspring. Well-provisioned sons may be especially likely to sire offspring if, as a result of receiving increased parental resources, they are better able to compete with other males for sexual access to females. Therefore, investing in sons when conditions are more favorable has the potential consequence of greater long-term genetic success than would investing in daughters. However, when conditions are less favorable, the potential reproductive benefits of investing in daughters will outweigh the investment costs, as daughters are likely to reproduce, even if they have been poorly provisioned. In these scenarios, it is preferable to produce and invest in daughters, who are likely to produce even a few offspring, rather than attempt to invest in sons, who, if poorly provisioned, may fail to attract a mate, thus producing no offspring.

The evolutionary theories developed by Robert Trivers have greatly benefitted the scientific understanding of animal behavior and cognition. His theoretical contributions to evolutionary biology have informed numerous hypotheses regarding the behaviors of sexually reproducing species, which have in turn produced substantial empirical knowledge.

## Introduction

Rodents (from the Latin *rodere*, meaning “to gnaw”) are the largest mammalian order (40%), comprising nearly 2300 species. They are diverse and abundant, occurring in nearly every terrestrial environment on Earth, apart from Antarctica. Their habits extend from burrowing, hopping, and climbing to swimming, and they show great diversity in diet, ranging from strictly herbivorous (e.g., capybaras *Hydrochoerus hydrochaeris*) to strictly carnivorous (e.g., grasshopper mice *Onychomys torridus*).

Rodents, like other animals, engage in costly behaviors, such as foraging, mating, territory selection, and defense, to access resources. To successfully access resources and avoid predation, rodents must be able to rapidly adjust their behavior based on the information they receive from their environment. Rodents rely extensively on olfactory cues to respond to environmental stimuli (Moriceau et al. 2010). Rodents then use their cognitive abilities to decode and use this information.

The word *cognition* (from the Latin *cognoscere*, meaning “to come to know”) covers a wide array of mental functions that relate to the acquisition, processing, remembering, and using of information (Dukas 2004). Until the 1950s, scientists generally avoided or dismissed animal behavior as having an underlying mental process. However, the Canadian psychologist Donald Olding Hebb was instrumental in recognizing that much of animal behavior is governed by underlying cognitive processes, laying down the foundations for understanding how behavior and cognition are related in animals and demonstrating that central processes operate in response to external stimuli (stimulus response).

Cognitive processes are essential for perceiving, recognizing, and discriminating between stimuli, for learning and decision-making, and for solving

problems, all of which are crucial for survival. However, while different types of cognition allow rodents to adjust their behaviors in response to different environmental stimuli (Dukas 2004), the approaches to studying and understanding rodent cognition are varied. To understand the ultimate (evolutionary history and adaptive significance) factors of cognition, it is useful to first gain an understanding of proximate (ontogeny and mechanisms) factors affecting cognition. The underlying neural machinery that supports cognitive processes is complex, and much of a rodent’s cognitive capacity is governed by underlying neuroendocrine mechanisms (Gilbert and Kesner 2002; Green and McCormick 2013). Specifically, these mechanisms and their influences may differ depending on the sex of the individual and may also change as the individual ages, resulting in fundamental changes in cognitive abilities occurring throughout the animal’s lifetime.

## Types of Cognition

### Perception, Recognition, and Discrimination

Rodents must be able to perceive stimuli. Perception is the process of interpreting and assessing environmental signals (Dukas 2004). Principally, rodents must perceive signals relating to food resources; otherwise they will starve, and they must perceive signals relating to predator presence; otherwise they will be predated. Recognition follows perception and can be defined as the repeatable and predictable response to environmental stimuli (Mendelson 2015). Even if the rodent encounters novel stimuli, it should respond in a predictable manner to a comparable, similar, stimulus that it has experienced previously. Recognition can be either innate (fixed in the genotype or acquired during early development) or learnt over time by associating the cue with its relative level of risk (Mendelson 2015). If a rodent cannot successfully perceive and recognize stimuli, it cannot learn the association between stimuli and outcome, leading to decreased fitness.

While perception and recognition are critical, discrimination between stimuli is not always essential. Discrimination is the ability to differentiate between stimuli (e.g., Object A is different from Object B) based on different memories that the rodent has associated with each stimulus. Discrimination is likely to be more common in situations relating to resource acquisition (i.e., knowing that food A has a higher nutrient content than food B), whereas it is likely to be less common in situations relating to predator avoidance, where generalized responses could be more effective in ensuring survival (Paulling et al. 2019).

### Learning

To improve the accuracy and/or success of the behavioral response, rodents should learn from each encounter with the stimulus. Learning refers to the acquisition of new information, including associations between stimulus (state of the immediate environment) and outcome, or behavior and stimulus (Dukas 2004). Rodents can learn in different ways. Individuals can learn by “trial-and-error” learning through reward and punishment (Sherwood et al. 2005), but they take a risk because of naivety (e.g., tasting new food runs the risk of it being noxious or unpalatable).

Alternatively, individuals in groups may learn via social learning, which involves observing the behavior or products of behavior of conspecifics or directly interacting with them (Heyes 1994). This reduces the costs associated with individual learning. Types of social learning include local enhancement, where individuals are drawn to an area by the activity and behavior of others; imitation, which is a process that involves accurately replicating behaviors shown by others; and observational learning, where individuals observe conspecifics, but do not directly duplicate their behaviors (Heyes 1994). Individuals in social groups have the opportunity to learn from demonstrators throughout their lifetimes (Heyes 1994).

### Memory

To learn, a rodent must remember the information or association for later reference. Memory can be categorized based on how information is stored

(episodic vs. semantic) or how long information is stored for (short-term vs. long-term). Episodic memory refers to the storage of episodes of contextual information. For example, episodic memory is related to what was happening when the information was learnt, where the information was learnt, who else was present at the time, and when the information was learnt (Templer and Hampton 2013). Semantic memory, on the other hand, is the storage of information without contextual detail (Templer and Hampton 2013).

Regardless of how the information is stored, information can be retained for either a short or a long period of time (Sherwood et al. 2005). Short-term memory is maintained only for short periods of time (seconds to hours). When new information is acquired, it is stored as short-term memory and accessed to avoid incorrect, repetitive behavior (Dudchenko 2004). For example, remembering which resource sites have been visited reduces repeated visits to empty sites, minimizing time spent foraging and reducing potential exposure to predators. However, short-term memory cannot store large amounts of information and is quickly forgotten if unnecessary for survival (Sherwood et al. 2005). In contrast to short-term memory, long-term (also known as reference memory or the memory of associations) is an association between stimuli and response that is maintained over longer periods of time (days to months/years; Dudchenko 2004). If information is important, and is actively recalled multiple times, it is consolidated into long-term memory, which can store large amounts of information (Sherwood et al. 2005). Long-term memory is activated through repeated exposure to a stimulus (i.e., Behavior/Stimulus A leads to Response B; Dudchenko 2004). The ability to remember information over long periods of time minimizes the costs of continually learning stable/constant associations, allowing more energy to be diverted to short-term memory acquisition.

### Decision-Making

Decision-making is the cognitive ability to evaluate stimuli or behaviors against the value of their outcome and then prioritize and choose the most appropriate action (Lee et al. 2012). Rodents

rarely obtain complete information about the value of different outcomes. Instead, they learn how to predict outcomes (Lee et al. 2012). Learning these relationships is easier in consistent, stable environments but becomes more difficult in unpredictable or dynamic ones (Lee et al. 2012). Decision-making leads to trade-offs between behaviors that could influence fitness (McFarland 1977). For example, if a rodent is hungry, it will evaluate the benefits of foraging against the cost of predation (McFarland 1977). The motivational state of the individual affects its decision to continue executing a current behavior or to change to a new behavior, with the final choice being determined by the current most demanding motivational state (McFarland 1977).

### Spatial Cognition

Spatial cognition is the process of using localization, sensory imagery, and decision-making to successfully navigate through environments (Arleo and Gerstner 2000). Successful navigation is necessary for any rodent that moves between fixed points in the environment, such as between nesting and foraging locations. To begin navigating, rodents must be able to generate and use a spatial representation of the relationship between their position and environmental landmarks, which requires the individual to regularly update its positional information as it moves through its environment (Gallistel 1989). This is initially done through dead reckoning, where the individual uses velocity as a function of time to determine a change in position, which allows for continuous feedback about location, even though it is a form of estimation that is prone to error accumulating over time (Gallistel 1989). Therefore, to correct this error, the rodent will use landmarks at known positions to recalibrate the spatial representation (Arleo and Gerstner 2000). Repeated navigation through the environment generates a cognitive map, which involves mentally configuring external stimuli (e.g., visual cues) into distinct environmental regions in the brain. This map is then stored as long-term memory to be accessed in the future (Arleo and Gerstner 2000).

### Social Cognition

Broadly speaking, social cognition is knowledge about conspecifics (Seyfarth and Cheney 2015) and includes those cognitive processes that are used to understand and interpret the social environment (Beer and Ochsner 2006). For example, social cognitive abilities are used to process social interactions and networks, and to engage in appropriate sexual behavior and mate choice, ultimately allowing the individual to determine who to interact with and how to interact with them (i.e., avoid or mate with; Kavaliers and Choleris 2017).

Social cognition is initiated by perception and social motivation, which is an individual's willingness to approach and interact with a social target, and then social recognition, learning, and memory allow for the formation of long-term attachments and hierarchies that are crucial for social functioning (Bicks et al. 2015). Importantly, social cognition involves a component of self-recognition, as the individual's understanding of "self" as a social object (Beer and Ochsner 2006) plays a critical role in the establishment and recognition of alliances and partnerships, which could function to reduce competition or aggression (Seyfarth and Cheney 2015). Conceptually, social cognition, therefore, consists of a suite of skills, ordered according to cognitive demand, which allow rodents to observe, perceive, and recognize other individuals, to remember past interactions and social relationships, and to attribute mental states (e.g., feel empathy) to other individuals (Seyfarth and Cheney 2015).

### Problem-Solving and Innovation

Accessing resources (e.g., food and mates) and avoiding predation require problem-solving. Problem-solving is the ability (acquisition of behavior or information) of an individual to access a reward (i.e., resources or goals) by either moving itself or manipulating an object. The ability to solve problems does not depend on higher-order cognitive ability (e.g., insight; Griffin and Guez 2014). Instead, to successfully problem-solve, the individual must (a) be motivated to engage with the task, (b) be flexible in its behavior to try different tactics if one strategy is not successful, and (c) learn and remember what

behavior successfully solved the task (Griffin and Guez 2014). While successful problem-solving generally occurs through either trial-and-error or social learning, rodents, such as guinea pigs *Cavia aperea f. porcellus*, can solve problems through innovation, which is the use of new behaviors or using existing behaviors in a new context.

## Cognitive Neuroendocrine Mechanisms

### Sensory Integration

The external environment provides an array of sensory cues that are perceived by the sensory organs (e.g., eyes, ears, and nose). Once received, this information is processed in associated regions of the brain. For example, the somatosensory cortex processes tactile (touch) signals, and the optic tectum and thalamus process visual information. The brain then stimulates appropriate neuroendocrine responses that drive the expression of specific behaviors (e.g., flee from a predator). Similar to the external environment, changes in the internal environment (e.g., hunger) stimulate a cascade of neuroendocrine responses that drive appropriate behaviors (e.g., foraging). All types of cognition rely on sensory integration.

### The Brain

**Hippocampus** The mammalian hippocampus is responsible for navigation and spatial cognition. Hippocampal grid cells are triggered when a rodent moves into a specific location within an environment, while head direction cells are triggered when the animal moves its head in a particular direction (Foster and Knierim 2012). These cell types work in tandem to generate a cognitive map via learning and remembering the stimuli associated with locations, which is used for navigation (Foster and Knierim 2012). The hippocampus is also associated with decision-making, as it organizes and retrieves information from short- or long-term memory storage (Dudchenko 2004), forms associations, and separates patterns (Gilbert and Kesner 2002). While hippocampal cells respond to visual, olfactory, auditory, and somatosensory information, they can only

process spatial associations, which means that other cognitive abilities are not affected by disruption to hippocampal functioning (Gilbert and Kesner 2002).

**Prefrontal Cortex** The prefrontal cortex also plays a crucial role in multiple aspects of cognition. Firstly, it is involved in executive functioning, including error detection, motor control, goal-directed learning, evaluating risk and reward, decision-making, and maintaining attention (Euston et al. 2012). Secondly, the prefrontal cortex is neurally connected to the hippocampus and works in association with the hippocampus to form short- and long-term memories (Wang et al. 2009; Euston et al. 2012). The prefrontal cortex first organizes information about the relationship between stimulus and response/consequence, which is then replayed repeatedly to consolidate the memory (Euston et al. 2012). If necessary, the hippocampus also gathers spatial information to associate this memory with a location (Wang et al. 2009). The prefrontal cortex then organizes behavioral plans and goal-directed behaviors to act on this information (Wang et al. 2009) and plays a role in recalling information when required (Euston et al. 2012). Thirdly, the prefrontal cortex is also used to maintain social interactions and behavior in rodents, due to its involvement in memory formation, and damage to this region is known to disturb social memory and motivation and can disrupt social learning in mice (Bicks et al. 2015).

### Hormones and Neurotransmitters

**Dopamine** Dopamine is a neurotransmitter (a chemical messenger that transmits signals across a chemical synapse) that influences many aspects of rodent behavior and cognition. Dopamine receptors are present throughout the entire forebrain, especially the basal ganglia, regulating motor and limbic processes and contributing to the coordination of different behavioral and cognitive processes (Nieoullon and Coquerel 2003). Different cognitive processes require different levels of dopamine receptor activity, which could result in dopamine

receptor stimulation impairing performance in one task, while enhancing cognition in another (Chudasarma and Robbins 2004). Furthermore, different concentrations of dopamine can also affect cognitive processes involved in the same task (Chudasarma and Robbins 2004). Consequently, dopamine acts as a neuromodulator by, for example, impairing the memory of stimuli that have already been investigated (Chudasarma and Robbins 2004).

Dopamine controls motivation, attention, and alternating between behaviors (Nieoullon and Coquerel 2003). For example, lesions to the nucleus accumbens and prefrontal cortex, with high dopamine receptor abundance, result in a lack of motor inhibition and disruption to behavior sequence organization, spatial orientation, and social interaction (Nieoullon and Coquerel 2003). Dopamine also contributes to the detection of novel stimuli (Nieoullon and Coquerel 2003) and assists with decision-making by relaying error signals to update reward prediction values (Lee et al. 2012). Dopamine also plays a role in learning and memory, mediating reward-related learning (Nieoullon and Coquerel 2003), and impacting spatial and working memory performance (Chudasarma and Robbins 2004).

**Corticosterone** Stress can affect behavior and cognition (Green and McCormick 2013). Once a stressor is detected, the hypothalamic-pituitary-adrenocortical (HPA) axis in the brain stimulates the release of corticosterone from the adrenal gland (Green and McCormick 2013). Stress can be acute, where corticosterone concentrations peak for short periods of time, or chronic, where corticosterone peaks for sustained, or frequently repeated, periods of time. In the rodent brain, the hippocampus, prefrontal cortex, and amygdala have the highest densities of corticosterone receptors (Green and McCormick 2013). Therefore, corticosterone affects spatial cognition, goal-directed behavior, working memory, emotional learning, and memory functions (Green and McCormick 2013). However, while acute stress can improve memory performance, as it is beneficial to remember aversive events, chronic corticosterone exposure may have a negative impact

on brain morphology, reducing the number of synapses and impairing signal cascades in the hippocampus and prefrontal cortex (Green and McCormick 2013).

**Oxytocin** Oxytocin is an oligopeptide (a small protein that contains only a small number of amino acids) that is produced in the hypothalamus and transported to different brain regions associated with social cognition, including the amygdala, olfactory regions, thalamus, hypothalamus, and hippocampus (Kavaliers and Choleris 2017). As a result, oxytocin controls and processes the response to social information, allowing for social recognition, learning, and memory to occur (Kavaliers and Choleris 2017). A disruption in oxytocin production, therefore, interferes with how rodents interact with conspecifics. Rodents without proper oxytocin function make poorer social choices (e.g., mice with low oxytocin do not avoid parasitized individuals, Kavaliers and Choleris 2017). Oxytocin is also involved in sexual, affiliative, and parental care behaviors, leading to individuals with impaired oxytocin expression showing poor mate choice discrimination or copying (Kavaliers and Choleris 2017).

## Developmental Effects: Age and Sex

### Age Effects

#### Physical Changes

As rodents age, they undergo developmental changes in their brain physiology and morphology, affecting their cognitive abilities. The most dramatic developmental changes are generally experienced during the first three weeks of a rodent's life, where the pup becomes a mature, independent individual (Moriceau et al. 2010). During these early stages, pups need to acquire the necessary information required for survival, and they experience changes in their learning preferences and abilities, for example, by quickly forming positive or negative associations with unfamiliar cues (Moriceau et al. 2010). Due to low corticosterone concentrations present at this stage, the amygdala is not yet involved in learning,

As the individual ages, corticosterone concentrations may rise, and the amygdala becomes more actively involved in the formation of associations (Moriceau et al. 2010). Despite not undergoing such drastic changes as juveniles, the cognitive abilities of mature individuals are still affected by the aging process. Some of these changes are due to changes in the vascular morphology and physiology of the brain. Aging brains experience an increase in capillary length and volume, thinning of capillary walls, and a reduction in blood vessel growth (Goldman et al. 1992). These physical changes, coupled with changes in secretion of the hormone vasopressin, affect learning and retrieving learnt responses as they reduce the amount of blood flow and nutrient movement in the brain (Goldman et al. 1992).

#### Stress Effects

Stress during early life stages can have long-lasting impacts on rodent cognition. Even in the womb, pups can be exposed to stress via the maternal environment. Corticosterone can cross the placental barrier, affecting the brains of fetal pups, and this stress experienced during the prenatal period can have a knock-on effect on hippocampal function during adulthood, leading to decreased learning abilities (Lupien et al. 2009). Early postnatal stress can also lead to changes in brain physiology and morphology. Prolonged periods of early postnatal maternal separation in pups affect corticosterone production pathways later in the adult hypothalamus, amygdala, prefrontal cortex, and hippocampus, leading to overstimulation of the HPA axis and cognitive deficits, such as an inability to recognize new objects (Lupien et al. 2009).

Adolescence is also a period of significant brain development. The HPA axis is more active during adolescence, and juvenile rodent brains, therefore, experience higher concentrations of corticosterone than adult brains (Lupien et al. 2009). Juveniles do not habituate to a stress like adults, taking longer to form negative feedback systems (Lupien et al. 2009). Consequently, chronic, unpredictable stress experienced during adolescence can result in lower hippocampal volume in adulthood (Lupien et al. 2009) and deficits

in hippocampal-dependent cognitive performance (Green and McCormick 2013), including performance in spatial tasks, such as the Morris water maze, and avoidance learning. However, environmental effects can, to a degree, mitigate the negative effects of stress experienced during this sensitive period. For example, housing young rats in social groups can reduce the effects of a social deprivation stress on hippocampal-dependent and prefrontal cortical cognitive tasks (Green and McCormick 2013).

Finally, chronic stress in adulthood may also have a negative influence on brain morphology and cognition of rodents. Chronic stress in adulthood results in the death of hippocampal neurons and prevents the production of new neurons in the dentate gyrus, thereby reducing hippocampal volume, which then negatively impacts learning and memory (Lupien et al. 2009). Unlike juveniles, however, adults may be more plastic in their response, showing a recovery and reverse of effects just a few weeks after the stressor has ceased (Lupien et al. 2009).

#### Sex Effects

Sex-specific patterns of gonadal steroid secretion, namely, testosterone (predominantly in males) and estrogens (predominantly in females), during specific periods in ontogeny may accompany the development of different brain regions associated with cognitive processes, such as the hippocampus. For example, infusing estrogen into the hippocampus improves memory in the object recognition task in female rats (Chisholm and Juraska 2013). Long-term increases in estrogen concentrations also improved performances in object recognition, spontaneous alteration, and matching to position tasks in female mice (Chisholm and Juraska 2013). Furthermore, hippocampal dendritic spine density is also increased in male rats in response to testosterone, which can have a corresponding enhancing effect on spatial learning and memory (Spritzer et al. 2011).

But sex differences in hormonal expression also vary with age and reproductive cycles or events. The expression of estrogen receptors in the hippocampus is dynamic, and estrogen concentrations change with both the estrous cycle and

with age. Synaptic remodeling of the hippocampus occurs repeatedly during the estrous cycle in response to ovarian steroids (Spritzer et al. 2011). Furthermore, birthing and raising pups enhance spatial cognition in female rats, most likely due to the action of estrogens on brain structure (Macbeth and Luine 2010). Age-related decreases in gonadal hormone concentrations are common to both males and females; however, testosterone in males can potentially better modulate the effects of cognitive decline via aromatization of testosterone to estrogen, leading to increased working memory (Spritzer et al. 2011).

Finally, stress affects cognition of males and females differently. Estrogen is known to alter or interact with the HPA axis, influencing the production of glucocorticoid hormones, with females generally having higher circulating concentrations of corticosterone as a consequence (Macbeth and Luine 2010). Interestingly, females may experience positive cognitive effects from increased corticosterone concentrations, showing heightened spatial working memory (Green and McCormick 2013), because oxytocin release is mediated by estrogen and can induce hippocampal plasticity over long periods (Macbeth and Luine 2010). Interestingly, highly sexually differentiated neurochemical changes are also observed in the dopaminergic system of the prefrontal cortex, the part of the brain critical for delete memory in rodents (Bowman et al. 2003). Male rats that experienced significant restraint stress showed decreased dopamine activity in the prefrontal cortex and amygdala that, combined with elevated corticosterone, resulted in impaired object recognition and spatial memory, whereas females stressed for a similar period of time in the same test showed no changes in dopamine activity and no impairment in cognitive tasks (Bowman et al. 2003).

## Conclusions

Rodent cognition is multifaceted, consisting of processes that identify, store, access, evaluate, and remember environmental information. Brain morphology and physiology, in particular, are the

underlying regulators of cognition, with some brain regions and hormones controlling a variety of cognitive functions. Cognitive processes naturally change with age due to changes in brain morphology and physiology, especially indirectly through stress effects. Finally, rodent cognitive abilities can differ between the sexes due to the differing effects of reproductive hormones on brain structure and physiological function. There is, therefore, a strong link between cognition and the neuroendocrine system, highlighting the importance of considering the physiological processes of rodents when studying their cognitive abilities.

## Definition

Communication is the exchange of information between a sender and a receiver that the receiver can both perceive and decode, as well as the use of that information by the receiver to make a decision.

## Introduction

Rodents are a diverse group of mammals that belong to the order Rodentia which are characterized by a pair of continuously growing incisors in the upper and lower jaws. There are over 2000 known species of rodents that are found across the globe in a variety of aboveground and subterranean habitats. Rodents vary in size, from the Baluchistan pygmy jerboa (*Salpingotulus michaelis*) weighing in at 5 g to the capybara (*Hydrochoerus hydrochaeris*), which weighs over 50 kg. Rodents also range in their sociability, with eusocial naked mole-rats (*Heterocephalus glaber*) living in large colonies and woodchucks (*Marmota monax*) living solitarily. In addition, mating systems range from monogamy in prairie voles (*Microtus ochrogaster*) to promiscuity in black-tailed prairie dogs (*Cynomys ludovicianus*). The diversity of living conditions in rodents led to the evolution of highly adaptable sensory systems used in communication (see “► [Rodentia Sensory Systems](#)”).

Rodents communicate information about identity, fitness, willingness to mate, location, food availability, and danger. This communication takes place during different social and asocial events, such as foraging, play, mating, aggression, or predation. Information can be relayed through touch, such as nose touching in yellow-bellied marmots (*Marmota flaviventris*), scent (scent marking in wild house mice (*Mus musculus*)), or another sensory modality. Modes of communication, or the dominant sensory modalities that an animal employs, are critical for understanding the evolution of an animal's behavior and the signal used during communication (see “► [Rodentia Sensory Systems](#)”). In this entry we will focus on different behavioral venues during which communication occurs in wild and laboratory rodents.

## What Is Communication?

Communication is a process in which one animal, the sender, transmits information to another animal, the receiver, subsequently causing a change in the receiver's behavior. There are two

requirements that must be met for an interaction to be defined as communication. First, the sender must be supplying information on purpose, and not by accident. In other words, communication is a transfer of information between two active parties. The second criterion is that the receiver must benefit from the information being received (Bradbury and Vehrencamp 1998). During communication, senders may present accurate and reliable information or try to deceive the receiver.

The basic unit of communication between a sender and a receiver is a signal. The signal is any visual, auditory, chemical, tactile, or mixed stimulus that leads to a change in the behavior of a receiver. This process usually occurs within a species, benefiting the sender and the receiver. One can assume that the sender and the receiver in this exchange likely have the same goals. However, signals can also be used by other species. For example, the great gray shrike (*Lanius excubitor*) uses scent marks left by prairie voles (*Microtus agrestis*) to find suitable hunting grounds (Probst et al. 2002). In this example, it is clear that prairie voles left scent-mark communication signals for their conspecifics, yet predators used these signals for their own benefit. Signals that are used to another species' detriment are known as cues. Receivers of the same or of a different species can exploit these cues through eavesdropping.

In some cases a signal may be “honest,” meaning that the sender is displaying reliable information. It has been suggested that rodents use scent marks as an honest form of communication, revealing information about an individual's identity, health, and reproductive condition. Wild house mice can modulate their scent marking based on factors such as health, diet, and mating opportunities. Zala et al. (2004) showed that female mice can reliably assess whether a male had a bacterial infection based on scent marks. In this study, reproductively active males left more scent marks than juveniles and consequently left more honest signals for female mice. Another example of honest signaling occurs between pups and mothers. Mouse pups emit isolation calls in the ultrasonic range prior to the onset of hearing in this species, suggesting that pup calls function to evoke a response. These calls are easy

to detect and lead to a retrieval response from the mother (Ehret 2005).

A “dishonest” signal, or misinformation, is when the sender is sending out false information to a receiver, likely to improve their own fitness. The most obvious area of deceit in the animal world is in mating behavior. One example of a dishonest signal occurs in Columbian male squirrels (*Spermophilus columbianus*) that produce a mating call post copulation that is acoustically similar to their predator alarm call (Manno et al. 2007). Male squirrels increase their reproductive success by monopolizing females and preventing their partner from copulating with other males. A mating call that is acoustically similar to an alarm call may occupy a rival’s attention and delay the female’s future encounters. Both male and female squirrels habituate to mating calls during the mating season, but they react by seeking cover and becoming more vigilant when they hear the same mating call during the non-mating season. This suggests that signals that are acoustically similar may convey different information during the mating season.

## Venues of Communication

### Foraging

Foraging for food is directly related to the survival of an animal in the wild. Thus, animals spend a significant amount of time looking for food. Early on, rodents must learn the location, identity, potential benefit, or danger of different food sources through olfactory, gustatory, and social cues (see “► [Rodentia Sensory Systems](#)” in this volume for more details). Rodent foraging choices vary based on interactions between factors such as nutritional value, water content of food, soil density and texture, ability to cache and recover food, and others (Randall 1993). It is commonly believed that rodents are prey species and thus consume grains and grasses. Nonetheless, many rodent species are omnivorous and will feed opportunistically (Wang et al. 2003), and some are predatory and will hunt other rodents and venomous arthropods (e.g., grasshopper mice, *Onychomys arenicola*) (Egoscue 1960).

Communication about food sources has evolved in a variety of social species. Perhaps the most famous example in communication is the dance of the honeybees, although social rodents are also capable of exchanging information about food through olfactory and auditory signals. For example, mice (*Mus domesticus*) and rats (*Rattus norvegicus*) have been shown to use olfactory cues from partners to obtain information about the food they are eating and its location (Galef 1994). This information aids in future foraging and feeding behaviors. In addition to olfactory communication, mice also utilize auditory information to understand the nutritional satiety state of a conspecific. In mice, ultrasonic vocalizations (USVs) have been observed during interactions between a food-deprived observer and a non-deprived demonstrator. Mice that were food-deprived vocalized extensively to non-deprived demonstrators, suggesting that auditory communication and satiety play a critical role during foraging (Moles and D’amato 2000).

Nonetheless, not all rodents want to reveal the location of food they found or collected; therefore special precautions have to be taken to prevent visual or auditory communication of food sources. Rodents that cache, or rodents that store food in locations hidden from members of the same or different species, spend a lot of time trying to conceal the location of their caches. Eastern gray squirrels (*Sciurus carolinensis*) forage and hide their food in small clusters during mid to late autumn. These animals show sensitivity to the presence of a conspecific audience during caching, visually concealing whether they are hiding food or digging, by turning their back to the observer (Leaver et al. 2007). In other words, gray squirrels try to intentionally throw their competitors off by concealing their true actions.

Foraging is an important activity for the survival of rodents. The choice to communicate or to conceal food locations varies within Rodentia based on the social structure and evolutionary adaptation of these mammals.

### Play

Social play, or play directed toward others, is a critical element of mammalian development and

is associated with social and emotional skills in humans and animals. Deficits in social play during critical developmental periods are correlated with childhood onset of neurodevelopmental disorders (e.g., autism, schizophrenia, and attention-deficit/hyperactivity disorder) and difficulties in communication. Social play is especially important for establishing social bonds and learning proper communication skills in rodents. Similar to humans, rodents engage in a variety of play behaviors, including playing with inanimate objects, solitary locomotor-rotational play, and social play. Competitive rough-and-tumble (RT) play, or play fighting, is a form of social play in which two animals compete physically for some sort of advantage, without physically harming one another. It is important to note that there is no universal standard for what level of roughness distinguishes play fighting from aggression (see “► [Play Behavior](#)” in this volume for more details). Communication during play is critical for understanding the social context and intention of the opponent.

Play communication may be one of the most complex communication systems seen in rodents. The prolonged reciprocal interactions that occur during play involve a situation in which the players are, often simultaneously, both signalers and receivers. Touch, scent, and auditory cues are emitted during RT play. In juvenile laboratory rats, the location of nipping can communicate the competitor's intention (Pellis and Pellis 1987). During play fighting, rats will touch/nip on their playmates nape of the neck, whereas a serious confrontation includes biting of the rump and other areas. Rats also communicate play through auditory cues. During play, rats of both sexes use high-frequency calls to communicate their intention and emotional arousal. These vocalizations are in contrast to low-frequency calls that are associated with aversive interactions and fighting (Burgdorf et al. 2008).

There are sex differences in play behavior and communication in rodents. Pellis and Pellis (1990) showed that male rats initiate more play-fighting encounters than female rats. Males also initiate more physical attacks and defenses with a male than a female. In contrast to rats,

juvenile male and female golden hamsters (*Mesocricetus auratus*) engage in rough-and-tumble-play approximately the same amount of time. Hamsters, however, are more likely to engage in play behavior with the same sex (Guerra et al. 1992). Male-female dyads spent a significant amount of time engaging in physical contact but very infrequently engage in play behavior (Guerra et al. 1992). In addition, female hamsters experience an earlier onset of aggression than males, suggesting that hormonal development may play an active role in absence of play behavior in heterosexual dyads (Taravosh-Lahn and Delville 2004). Together these findings suggest that play is critical for communication development in social rodents and may serve different functions in males and females.

### Mating

All species of animals that reproduce sexually must search for suitable mates. Communicating sexual receptivity and fitness is an efficient way to identify a potential mate and to avoid aggression. Rodentia mating systems range from monogamy to polyandry and require complex communication venues while searching for and/or maintaining a mate.

Olfactory signals are frequently used by rodents to communicate reproductive condition to conspecifics. Specifically, females that are approaching estrus (an active reproductive state) are more likely to leave scent marks than females in a non-estrus state. In addition, female scent marks are more attractive to conspecific males while females are in estrus. Females may also change who they communicate with during estrus. For example, female golden hamsters leave more scent marks in dominant male territories and create scent trails leading the dominant male to her burrow. Scent marks can also provide an honest signal to a potential mate. As previously mentioned in the *Introduction*, female mice can assess whether a male had a bacterial infection based on scent marks. In addition, females can determine whether the male has had a high-quality diet and what their present nutritional status is. Meadow voles (*Microtus pennsylvanicus*) show a preference for scent marks left by high-quality

diet-consuming conspecifics of opposite sex (reviewed by Ferkin 2018).

Olfactory cues are long-lasting forms of communication. However, visual and auditory modes of communication contribute to mate choices. In guinea pigs (*Cavia porcellus*), there is a pre-copulatory visual “rumba” display in which the male shifts his weight from one hindleg to the other to produce a rhythmic swaying in front of the female. The execution of this mating display is critical during mate choice, although males perform this dance for both familiar and novel females (Cohn et al. 2004). The effectiveness of this presentation is important during the female’s choice. In addition, many rodents engage in tactile (grooming, sniffing, licking) and auditory communication prior to, and during, mating. Rats emit high-frequency USVs associated with positive affect and reward prior to and during mating. The mating is usually concluded by a low-frequency ultrasonic vocalization associated with aggression. This aggressive auditory signal may function as a deterrent for other males (Burgdorf et al. 2008). In naked mole-rat colonies, queens are the only females that mate within the colony. Queens mate with a few males in order to increase genetic diversity in a subterranean population. Mole-rat queens produce a variety of vocalizations that function to attract males and solicit mating with the fittest males (Pepper et al. 1991).

Rodents use a combination of modalities to communicate reproductive fitness and to attract potential mates. The effectiveness of these signals is reflected in the reproductive success of rodents throughout their evolutionary history.

## Aggression

Aggression is a complex overt behavior that evolved in the context of animal’s survival and fitness. Aggressive interactions involve auditory, visual, olfactory, and tactile communication signals. Aggressive behavior is characterized by physical damage whenever two or more animals are in conflict over access to a mate or food, defending a territory, or their position within a social hierarchy. Aggression can be categorized into two distinct classes: offensive and defensive. Offensive behavior is initiated by the aggressor

intending to cause physical and social damage to the opponent. Defensive aggression is the counterpart to the abovementioned interaction, in which an animal doesn’t approach the opponents or inflict intentional damage but could cause harm defending oneself (reviewed by Takahashi and Miczek 2014).

There are broad similarities in features of aggressive behavior across Rodentia, related to maternal or territorial defenses or the establishment and maintenance of social status within a group. There are also notable sex differences in the contexts during which aggressive behavior occurs. Males tend to show aggression during territorial and social dominance encounters, while females may establish territories but tend not to defend them with aggressive behavior. Females also express offensive and defensive aggression during maternal periods, in which the mothers defend their young against intruders (Takahashi and Miczek 2014).

Communicating aggression ahead of time can minimize the physical damage, loss of resources, and can provide long-term survival advantages to rodents and other animals. For example, laboratory mice (and numerous other rodents) of both sexes scent mark territorial boundaries with urine, thus avoiding unnecessary aggression and its consequences. In some non-laboratory rodents, communication of aggressive behavior is activated hormonally and is correlated with pair-bonding. Adult prairie voles (*Microtus ochrogaster*) are monogamous rodents that communicate aggression and dominance similarly to mice through scent marking, visual displays, and vocalizations. In contrast to mice, aggression in prairie voles is influenced by social experience, with sexually naïve male voles choosing to nonaggressively interact with a male intruder through sniffing and vocalizing, rather than attacking them. However, following a mating-induced pair bonding, males display high levels of offensive and defensive aggression and communicate aggression reliably toward conspecifics other than their mate (Winslow et al. 1993).

Another example of aggression communication in rodents occurs in fox squirrels (*Sciurus niger*). Adult fox squirrels continuously compete

for food and other resources in their overlapping home ranges, making it critical to communicate aggression without engaging in potentially dangerous or deadly interactions with their neighbors. Squirrels communicate aggression using a variety of modalities. For example, squirrels can use a combination of visual signals, such as tail fluffing and foot stomping, vocalizations (audible vocalizations and tooth chattering), and olfactory cues to deter an opponent or warn others of an intruder or a predator. Interestingly, tail motion has been used extensively to assess communication of aggression and irritation in squirrels in both field and laboratory settings. Rapid tail jerking and fluffing has been observed in irritating but nonaggressive interactions between a squirrel and a conspecific or heterospecific intruder. This tail motion may be a visual warning signal. More serious aggressive interactions and disturbances are associated with flexible waving or flagging of the tail. In the laboratory setting, tail motion has been used to measure aggression, irritation, and frustration in a squirrel during an operant task. If a squirrel performed a task, such as pressing a lever, they learned to expect a reward of high nutritional value over time. In a task where reward value was changed unexpectedly, squirrels expressed frustration and irritation. Animals would use tail flagging during trials in which they received a reward of lesser nutritional value or no reward at all (Delgado and Jacobs 2016). Together studies of the communication of aggression suggest that signals of aggression can be used to gain insight into emotional and cognitive states of rodents.

### Predation

Predation (or predatory aggression) is an interaction between two animals in which one or multiple animals (predators) kill and eat another animal or animals (prey). Predatory aggression is primarily driven by appetite mechanisms. Generally, rodents fall into the category of prey species that have evolved specific adaptations necessary for survival in the presence of predators. These adaptations enable them to recognize when predators are present, avoid and defend themselves against predators, and communicate the presence of such danger to their conspecifics.

Social rodents have evolved various anti-predator adaptations which allow an individual animal to reduce the time necessary for “lookout” or vigilance behaviors. One way to reduce individual vigilance is through sharing “lookout” duties with others and communicating about possible dangers using signals that all conspecifics, and some heterospecifics, can understand. Perhaps the most famous form of communication about predators is alarm calling. Alarm calls are auditory signals in response to danger produced by social rodents and other animals. Over 20 diurnal rodent species have been observed producing alarm calls, although some nocturnal species engage in alarm calling as well (e.g., the plains viscacha, *Lagostomus maximus*). These vocalizations are loud warning calls, varying in duration from several utterances to prolonged bouts, that create an escape opportunity for conspecifics (reviewed by Blumstein 2007).

Alarm calls may also function to deter predators from attacking since they have been exposed. Banner-tailed kangaroo rats (*Dipodomys spectabilis*) are desert-dwelling rodents that engage in foot drumming (e.g., the repeated striking of a hind foot or feet on the ground) as a form of alarm communication. Male and female rats of all ages have been observed engaging in foot drumming in response to snakes. In addition to foot drumming, rats responded to snakes with alert postures, kicking sand and jumping back. Kangaroo rats engage in a different anti-predator behavior upon detecting aerial predators, emitting a single-note alarm call and escaping into their mound. These different communication signals likely convey the identity of the predator but also alert the predator that they have been detected. Snakes are sensitive to low-frequency vibrations caused by foot drumming and often retreat when exposed to low-frequency vibrations (Randall and Stevens 1987). Similarly, rattlesnakes (*Crotalus horridus*) leave their ambush sites and move to a more distant location if they detect a visual anti-predator display from rodents or birds (Clark 2005).

Rodents can also utilize olfactory cues to communicate the presence of a predator and other dangers to their conspecifics through the release

of alarm pheromones (APs). Alarm pheromones are chemo-signals present in scent marks that warn conspecifics about possible dangers. Experiments in mice showed that individual mice can identify conspecifics that experienced a stressful event based on the presence of AP in their urine. The receivers of this olfactory signal exhibit increase in vigilance behaviors similar to predator-response behaviors (Rottman and Snowden 1972).

Studies on predatory communication give insight into how rodents have adapted over time in order to avoid predation.

## Conclusion

Communication is defined as a transfer of information from a sender to a receiver. This entry has examined some of the mechanisms of and contexts in which rodents communicate. In general, rodents utilize auditory, visual, olfactory, tactile, and mixed sensory modalities to exchange honest and dishonest signals with conspecific and heterospecific receivers. The preferred channel of communication varies with context (e.g., foraging) and species (e.g., domestic mice vs. prairie dogs). Different communication strategies reflect evolutionary adaptation and natural history of an individual rodent species and the whole Rodentia order.

## Rodentia Diet

Mystera M. Samuelson

Animal Behavior Core, Department of Comparative Medicine, The University of Nebraska Medical Center, Omaha, NE, USA

Rodents are the most diverse mammal group and are found in nearly every terrestrial ecosystem on the planet. Thus, it is not surprising to find that rodent diets are as diverse as the Rodentia family itself, evidenced by their unique foraging

behaviors, dentition, and other unique qualities (Hunter and Jernvall 1995).

Optimal Foraging Theory holds that animals should prefer food items which are high in protein, and low in fiber. To account for the large number of mammalian herbivores, this approach to studying animal nutrition would also suggest that herbivores would have to develop behavioral and/or physiological strategies designed to compensate for the lack of protein in their primarily fiber-focused diets. This could include, but is not limited to, higher energetic costs for digestion, lower metabolisms which would preserve energy expenditure, and an increased need for food intake in order to maintain adequate energy levels. Herbivorous rodents have similarly altered their locomotor strategies to compensate for their decreased metabolisms (Zhang et al. 2016).

Maternal fiber intake during pregnancy and lactation is directly related to offsprings' energy intake and body mass in adulthood. Additionally, rodents whose mothers consumed a low-fiber diet experienced an improved glucose tolerance, but also suppressed fat accumulation (Zhang et al. 2016). While this may sound appealing to the modern human, for many species of wild mammal, the reduced inability to accumulate fat may be the difference between surviving and not surviving a long winter, for example. Thus, it is unknown whether the impact of decreased maternal fiber intake is practically for the evolutionary fitness of offspring.

Sex differences in diet can not only be attributed both to the energetic challenges associated with parturition and lactation, but also with the ranging habits common to each sex in most species of rodent. Specifically, males are likely to exhibit increased dietary diversity as a result of their broad ranges and associated travel. Alternately, females typically exhibit high site fidelity as a result of the needs of rearing young. Thus, females are likely to utilize familiar territory and known food sources to provide for herself and young (Ferrando et al. 2019).

Diet not only shapes the ethology of rodent species, but also impacts – and is impacted by – physiology. This is most evident when one considers dental morphology; particularly the morphology of the first upper molar has been

demonstrated to differ significantly in shape as a result of the target species' diet in murine rodents. This knowledge assists researchers in studying the evolution of murine diets and by extension assists also in forming inferences regarding their behavior and role in the ecosystem. Similarly, other physiological features such as ear size and olfactory ability may differ between carnivorous and herbivorous rodents as a result of their unique foraging tactics (Gómez Cano et al. 2013).

Carnivorous rodents can be further divided into vermivores, insectivores, and the amphibious rats. Carnivorous rodents share unpigmented tooth enamel particularly on the anterior surface of the incisors, a smoothing of the occlusal surface of molars, and typically exhibit fewer molars than do their herbivorous relatives (Rowe et al. 2016). These evolutionary adaptations indicate a decreased need for the breakdown of hardened plant materials through gnawing and mastication.

Rodent foraging strategies frequently bring them into conflict with humans, resulting in an ever-expanding pest-control industry designed to exterminate unwanted rodents. In order to deter depredation on crops and/or unwanted cohabitation with rodents, reducing attractants is key. To deter herbivorous rodents, the planting of vegetation high in terpenes is likely to deter foraging behaviors and habitation in most herbivorous rodent species (Skopec et al. 2019). Similarly, omnivorous and carnivorous rodents can be deterred by determining the likely prey items attracting the unwanted rodents and reducing the key attractants for those prey species.

As one would expect, dietary preferences, and the related evolutionary adaptations, are directly related to the overall fitness of a species – impacting behavior, habitat preference, and other key factors. Developmental growth rates, and by extension survival rates as well as fecundity, are directly related to adequate nutrition. Rodents living within the same ecosystem often have different nutritional needs which result in species-specific preferences allowing for variation across species within an ecosystem. For example, in Alaskan microtine rodents such as brown lemmings, collared lemmings, and voles, each has developed a dietary preference which yields

optimal growth rates for that particular species. Brown lemmings tend to exhibit a preference for sedges, while collared lemmings tend to exhibit a preference for willows, and voles for both sedges and willows. However, all three species avoid those food items which, although not necessarily considered poisonous, do not yield an optimal growth rate such as ericaceous evergreen shrubs. These developed preferences appear to be unrelated to the availability or taste of the deleterious food item(s) (Jung and Batzli 1981). Similarly, dietary preferences do change seasonally, depending upon both the changing availability of various food items, and the changing nutritional needs of a species throughout the year and breeding seasons (Gasperini et al. 2018).

## Rodentia Life History

Gisela Sobral

Departamento de Reprodução Animal, Faculdade de Medicina Veterinária e Zootecnia,  
Universidade de São Paulo, São Paulo, Brazil

## Definition

Set of traits that are important to the life of rodents.

## Introduction

The order Rodentia is the most diverse among mammals and is divided from four up to seven main groups depending on the authority, but Wilson et al. (2016) separated it into five groups; namely, Anomaluromorpha, Castorimorpha, Hystricomorpha, Myomorpha, and Sciuromorpha that, altogether, comprise nearly half of the mammalian species. The majority of species are small-bodied (<5 kg) Myomorpha rodents, although some are as large as capybaras, which may reach up to 66 kg (Caviomorpha group).

The small-bodied rodents show a similar set of life history traits, such as high metabolic rate, short gestation length, weaning, and sexual maturity attained at early age, large litters produced at short intervals with brief parental care, fast growth, short life span, and high mortality (Promislow and Harvey 1990). Although some traits are fairly conserved, others vary widely. Variation across taxa will be presented first (Section “[Life History Variation Across Taxa](#)”), followed by variation within taxa, i.e., non-phylogenetic sources of variation (Section “[Life History Variation Within Taxa](#)”). Most of

the information regarding Section “[Life History Variation Across Taxa](#)” can be found in Wolf and Sherman (2007), Patton et al. (2015), and Wilson et al. (2016). Additional information that was not found in these books will be presented with its respective reference accordingly.

## Life History Variation Across Taxa

### Anomaluromorpha

*Size, Habit, and Habitat.* Sometimes included in the Hystricomorpha group depending on the authority, this is an African clade, composed by the rare anomalure flying rodents (not closely related to the flying squirrel from Sciuromorpha group) and the springhares, *Pedetes* spp. They may reach 90 cm and weight 1.8 kg. All anomalures are primarily herbivorous and feed on fruits, seeds, and leaves, but some colonial species may ingest insects. As for springhares, they are large, bipedal, and saltatorial rodents, reaching 50 cm and weighing 4 kg, considered as the third largest African rodent (surpassed by the porcupine *Hystrix* and the cane rat *Thryonomys*).

*Breeding Period.* With scarce information, anomalures seem to be seasonal breeders. They give birth in tree hollows, and there is not much else known regarding other reproductive biology aspects. As for springhares, females are polyestrous (fertile at multiple times in a year), and pregnancies have been recorded throughout the year, although depending on rainfall and grass production.

*Litter Size, Gestation Length, and Weaning.* Females are more frequently found with only one young, but there are records of up to four pups in *Anomalurus pelii*. Gestation of springhares is long, around 3 months, with an interbirth interval of 101 days. Gestation of springhares is long, around 3 months, and interbirth interval is of 101 days, and thus they are able to produce 3 to 4 litters a year.

*Sexual Maturity and Longevity.* Springhares reach sexual maturity around 2 years of age, reproducing 7 years in the wild, and living for 19 years in captivity.

*Mating System.* The matings for springhares are unique: two males chase a female, and the fastest male has the chance to mate with her, forming a vaginal plug and preventing the second male to mate.

*Parental Care.* The *Anomalurus beecrofti* mother carries the young with her, but if in the nest, *A. derbianus* parents regurgitate food for the young. Birth occurs in chambers, and offspring is considered precocial, covered in fur, and able to move within a few hours after birth.

### Castorimorpha

*Size, Habit, and Habitat.* Castorimorpha is composed of unique rodents, such as pocket gophers, kangaroo rats, pocket mice, and beavers. The pocket mice and kangaroo rats can be tiny, measuring up to 35 cm, but many other representatives are large, robust and semi-aquatic rodents, such as the beaver, weighing about 20 kg and measuring 120 cm. The pocket gopher (*Thomomys* spp.) is a solitary subterranean rodent, hard to observe and study in the wild, and the other Castorimorpha members are solitary too, with a few exceptions. Conversely, beavers are highly social, build large dams in which they rest, breed, and interact socially with family members. Beavers are active mostly at night and only observed outside the dam while foraging or obtaining wood for dam construction. Therefore, there is little information on these elusive species. They occur from the temperate grasslands to the deserts and tropical forests.

*Breeding Period.* Some species are highly seasonal breeders, such as the pocket mouse *Heteromys anomalus*, where males present testicular recrudescence and both sexes are sexually active at the same time. Beavers reproduce only once a year and females come into oestrus for a very brief period (12–24 h).

*Litter Size, Gestation Length, and Weaning.* When compared to other similar-sized relatives (e.g., Myomorpha rodents), litter size of this group is smaller, with 2–4 young as the most common litter sizes. Additionally, gestation is longer, maturation is slow, and the number of litter per year is also smaller (around one). Tinier Castorimorpha species tend to have larger litters

(up to 7 in *Thomomys*), while larger species have smaller litters (up to 2 in *Orthogeomys* or up to 3 pups in *Geomys*). Beavers have a long gestation length of about 100 days, and the nutria *Myocastor coypus* may delay birth in the face of a threat.

**Sexual Maturity and Longevity.** Beavers attain sexual maturity at about 2 years of age, when they disperse from their natal group. Tropical and subtropical pocket and kangaroo rats may live short lives and reproduce only once, while others breed several times. Gophers are roughly unknown, but it is estimated that larger species might live for 3 years or more. Beavers can live up to 24 years in captivity.

**Mating System.** Beavers seem to express genetic monogamy (exclusive monogamy) as they mate exclusively with only one partner (not confirmed by DNA analyses). Pairs remain together for up to 6 years, with dissolution resulting from death of partner rather than desertion. Although monogamy is the main pattern, density may influence mating system. In low densities, individuals mate with a single partner, while at higher densities, they mate with multiple partners. This strategy is called facultative monogamy. Spiny pocket mice exhibit the highest secondary sexual dimorphism in which males are 40% heavier than females that possibly results from intrasexual competition for females.

**Parental Care.** Beavers show high degree of biparental care and extensive paternal investment in young. They are highly territorial, and older family members live together in a group. During parturition, fathers and older offspring may help protect newborns and lick them. Afterwards, young individuals may beg for food from older individuals. In other representatives of this group, such as gophers and kangaroo rats, the most common pattern is lack of male paternal care.

### **Hystricomorpha**

**Size, Habit, and Habitat.** This group comprises some unique rodents, such as the largest living one, the capybara (*Hydrochaerus hydrochaeris*); second largest, Patagonian maras (*Dolichotis patagonum*), the only eusocial mammal; naked mole-rat (*Heterocephalus glaber*); porcupines;

and a wide range of other South American rodents. Their biology also varies greatly, from being aquatic to rock dwellers and from nocturnal to diurnal. One almost ubiquitous aspect of this group is their high propensity to group living (up to 300 individuals in the naked mole-rat), although some may be solitary (*Cavia magna*). One of the Hystricomorpha representatives, *C. intermedia*, is considered as one of the rarest mammalian species on Earth, while the Guinea pig (*C. porcellus*) is commonly domesticated as a pet and laboratory animal.

**Breeding Period.** The most common pattern is to reproduce year-round. Gestation is around 2 months, and some females may produce three litters per year. Reproductive inactive females (e.g., *Cavia gundi*) present a vaginal closure membrane, being sexually inactive most of the year, but females are able to store spermatozoa in their genital tracts for 2 months. A very unusual behavior for rodents but present in this group is the exhibition of sexual activity outside of the oestrus period, as seen in porcupine species (Cape porcupine *Hytrix africaeausstralis* and Indian crested porcupine *H. indica*). In cane rats, *Thryonomys* spp., oestrus cycles seem erratic, and thus, researchers think that their ovulation is induced (i.e., it requires an extra stimulus for ovulation, such as male presence or the physical act of copulation).

**Litter Size, Gestation Length, and Weaning.** Like Sciuromorpha, this group has a smaller litter size. Singletons are reasonably common, with litter size ranging from one to four pups per female (but exceptions occur, as in nutria *Myocastor coypus*, which may give birth to 12 pups). Unlike its small-litter-size relative, Hystricomorpha has only two pairs of mamma. Naked mole-rats are the exception. Queens raise litters equal to the number of mammae (12), and litters of 28 offspring have been reported in both field and lab colonies. Such extremely large litters are possible because pups take turns at nipples, and colony members share food with them to protect the queen. Gestation is generally long (around 5 months in Cane rats *Thryonomys*, 4 months in the porcupine *Hystrix*, and 7 months in the North American Porcupine *Erethizon*

*dorsatum*) and suckling continues for another 2 months in porcupines, 1 month in cane rats, or 54 days in New World hystricomorphans. In smaller species, gestation is generally shorter, except for ashy chinchilla rat (*Abrocoma cinerea*), which is exceptionally long for a rodent this size, lasting 4 months.

**Sexual Maturity and Longevity.** Sexual maturity is reached as early as 60 days in *Cavia intermedia*, or around 1 year of age in *Hystrix*. If born in the beginning of the breeding season, some females may breed at an earlier age (30 days in *C. magna*), and some may stay reproductively active until 16 years of age (e.g., naked mole-rat). Some hystricomorphans are long-lived in captivity; for instance, 14 years in Maras (*Dolichotis patagonum*), and 20 years in Old World porcupines (*Hystrix*). In gregarious or social porcupines, there might be reproductive suppression of subadult/subordinate individuals, such as the Cape porcupine (*Hy. africae australis*) and the naked mole-rat (*He. glaber*).

**Mating System.** Mating systems can be polygynous, with one male accompanying one or two females. Thus, strong sexual dimorphism has been observed in this group (e.g., *Cavia aperea*) with males 15% heavier than nonpregnant females. Another common mating system is monogamy, as observed in some Old World porcupine (*Hystrix*) species. Interestingly, in naked mole-rats, the queen solicits copulation with one to three males (the older, heavier, and less familiar ones), instead of intrasexual competition (male-male combat), so that multiple paternity is common. An unusual pattern for mammals is present in North American porcupines *Erethizon dorsatum*, in which males are the philopatric sex, while females disperse.

**Parental Care.** Hystricomorpha rodents have particularly precocial neonates (covered in fur, eyes open, and fairly developed locomotion). Young may complement milk with solid food almost immediately after birth. Despite that, nursing can occur for weeks or months, but parental care is intense and long in porcupines, with males caring for the young as much as the mother. With mainly precocial young, some mothers allow offspring to feed from their mouths, as seen in green

acouchi, *Myoprocta pratti*. Interestingly, in naked mole-rats *Heterocephalus glaber*, parents shove infants around the nest in order to teach pups to respond to a threat by fleeing. A characteristic of precocial young is their high mobility. Therefore, maternal contact calls may be frequent in this group. Yet, despite being highly social/gregarious, some Hystricomorpha species may present no paternal care at all (e.g., *Galea spixii*).

## Myomorpha

**Size, Habit, and Habitat.** Myomorpha is one of the most diverse rodent groups, including nearly a fourth of all **Mammalian** species. It includes rats, mice, gerbils, lemmings, voles, and hamsters. Despite, or due to, its diversity, many species lack proper life history information. They are generally small (less than 5 kg) and nocturnal and may feed on seeds, leaves, fruits, invertebrates, and fungi. Their habits vary greatly with respect to locomotor habit, such as arboreal, semi-fossorial, semi-aquatic, and saltatorial. They can be found from sea level up to 3,000 m high in the Andes. Those that live in cold places and/or in high elevations may show activity during the warm periods of the day. They are cosmopolitan, inhabiting all continents, except Antarctica, and many can live close to human settlements, influencing – and being influenced by – human activities.

**Breeding Period.** Their reproduction is closely related to rainfall and primary production, breeding seasonally, and somewhat after a rainfall peak, but some may breed year-round. Young individuals appear later on, when the primary production is still high after the rainy season. Voles and lemmings are known for their marked population fluctuation, while some are mostly in high densities (e.g., *Necromys lasiurus*) and others seem to be always in low densities (e.g., *Andinomys edax* and *Irenomys tarsalis*).

**Litter Size, Gestation Length, and Weaning.** Litter size generally ranges from 2 to 6, but a litter of 13 young has been registered in the wild, and one of 20 young has been recorded in captive colonies of rats. Gestation period is similar across taxa, lasting around 21 or 22 days. Weaning occurs around 20 days of pup age, and nipple

fidelity has been observed in prairie and pine voles. Some species present postpartum oestrus, breeding again right after giving birth (e.g., *Necromys lasiurus* Almeida et al. 1981). Some females may show several infertile ovulation cycles before becoming pregnant.

**Sexual Maturity and Longevity.** Young individuals may reach sexual maturity soon after weaning (~20 days). Their life span is possibly no longer than two winters, or of a couple of years in the wild, but some may live up to 5 years in captivity.

**Mating System.** Myomorpha presents some famous monogamy examples, such as the vole *Microtus ochrogaster*, the gerbil *Meriones unguiculatus*, and a couple of deer mice species *Peromyscus* spp. Yet, recent findings show that none of these males were able to fully monopolize a female, as multiple paternity has been detected in litters of both *Microtus* and *Meriones*, but not in *Peromyscus*, in which genetic monogamy was detected with certainty (Solomon et al. 2004).

**Parental Care.** Despite being rare in this group, some species have direct male parental care. Male muskrats *Ondatra zibethicus* are famous for constructing and maintaining burrow structures in the wild. Males of this species and of pine voles *Microtus pinetorum* feed juveniles. In white-footed mice, *Peromyscus leucopus*, fathers accompany weaned young on foraging trips. Some fathers may perform grooming of young at the anogenital region to stimulate urination and defecation, a critical behavior for newborns, a behavior observed in spiny mouse *Acomys cahirinus*, Djungarian hamster *Phodopus campbelli*, Siberian hamster *Ph. sungorus*, and prairie vole *Microtus ochrogaster*. Biparental care has been seen in prairie voles, where a mated pair may be quite aggressive to intruders, despite their small size, and both mothers and fathers coordinate nest visitation so that pups are often not left alone. One interesting behavior observed in social voles *M. socialis guentheri* is the so-called forced babysitting. The father (mainly) drags the mother to the nest to stay with the pups, while he leaves the nest.

Because nest building before parturition is frequent in this group, this feature deserves more attention. When babies try to venture out of the

nest, mothers tend to retrieve them, a common maternal behavior. Mothers with large litters spend less time in the nest, a reality of Myomorpha mothers with their up to 13 young per litter. Some explanations converge to the need that they have to acquire more food for nursing so many young, in order to meet their nutritional demands. Another hypothesis, however, is related to the maintenance of body temperature. Larger litters require less help to maintain individual body temperature as they can huddle to each other. In addition, huddling with large litters may lead to hyperthermia in mothers.

### Sciuromorpha

**Size, Habit, and Habitat.** Sciuromorpha is composed of all the world's squirrels, as well as prairie dogs, marmots, and dormice. Squirrels are mainly diurnal and adapted for life in trees, but prairie dogs and marmots are burrow dwellers. Body size varies from 115 mm (BL) and 45 g to 340 mm BL and 5 kg. Sciuromorpha inhabits a wide range of environments, such as the temperate zones in North America and Europe, to the tropical forests in South America, and the savannahs in Africa. Yet, the life history of this group is still poorly known. Some species may be solitary, highly communal/social, or both (depending on ecological factors), but marmots and prairie dogs are mostly gregarious.

**Breeding Period.** Difficult to collect and observe for long periods, everything else regarding Sciuromorpha life history is based on scattered observations. These observations suggest that breeding period can occur throughout the year in some tropical species, once a year in temperate environments or bimodally in some Amazonian species. No breeding was observed when food availability was low, which suggests that reproductive failure is closely related to food availability, as in many other groups.

**Litter Size, Gestation Length, and Weaning.** Litter size ranges from 2 to 4 in most species, despite that some may present up to 12 mammae. The largest litter has been observed in the antelope ground squirrel *Ammospermophilus* and dormice (14 pups). Gestation lasts less than 60 days, and some females breed up to three times in their lifetime. Length of gestation and lactation period

together is of 15–16 weeks in some species. This group presents typical altricial young (the opposite of precocial pups from Hystricomorpha, see above). Altricial young is characterized by pups that are born with eyes closed, naked, low locomotor development, and highly dependent on parents. Therefore, the degree of parental care in this group is higher as altricial pups need intense care and for a longer period.

**Sexual Maturity and Longevity.** Most species mature during the first year of life, but some colony-living species (prairie dogs and marmots) delay their maturity, extending until the 4th year of life. Longevity is not known for most of the species, but one squirrel species (*Notosciurus granatensis*) was recaptured for 6 years, with approximately 7 years of age, and marmots may live up to 15 years (very rare).

**Mating System.** Within this group exists one of the most iconic reproductive strategies observed among rodents. Cape ground squirrel *Xerus inauris* males have one of the largest penis/testicle ratios within Mammalia, related to a promiscuous mating system and high sperm competition. As for other species, males may experience testicular recrudescence (testicles reduced in size and positioned inside the abdomen, with diminished or absence of spermatogenesis). As for other representatives, such as prairie dogs, there are many polygynous species, in which females mate usually with only one male, even though living in groups with other males.

**Parental Care.** Biparental care is not common, even in gregarious species like prairie dogs and marmots, in which male care is restricted to defense of territory. Conversely, maternal care is intense and complex in this group. Sometimes a mother may bring food to the nest, such as groundhog *Marmota monax*, and there are species (e.g., Belding's ground squirrel *Urocitellus beldingi*) with complex communication skills, with mothers warning their young with specific calls to advise that a predator is close.

## Life History Variation Within Taxa

Although life history traits deal with important parameters, they are quite plastic, varying among

species, among individuals of the same species, and in the same individual through time. Rodents are known for displaying great plasticity in their life history traits, presenting great population fluctuation and responding quickly to a wide range of environmental changes.

## Age and Size-Related Variation

The life history of individuals is not fixed throughout their lifetime, so that age, size, and experience are the most important sources of variation. Since age is closely related to experience and size, the three are interconnected, and it is difficult to separate each. For instance, the more litters a mother has, the more experienced she gets and some presents a higher success in rearing larger or subsequent litters. More litters also means the female is getting older. Regardless of which specific effect rules, it has been observed that reproductive success is correlated with the age of the mother in beavers (Wilson et al. 2016).

Age is not the only way of acquiring experience. Another way is through alloparental care, in which an individual helps caring for the young that are not its own. The extent to which alloparenting occurs in some species is still under discussion. Adult prairie voles did not show higher survival success in pups that were raised with alloparental care, but they developed faster (Stone et al. 2010; Wilson et al. 2016). However, few studies have addressed the paternal experience in relation to parity, as in experienced males having or not having more offspring. Apparently, it had little effect in prairie voles, white-footed mice, deer mice, and Norway rats (Wolff and Sherman 2007).

Age influences growth, and association between size and life history traits is widespread among animals. Larger females show a higher degree of maternal care (Ralls 1976), while larger males are better at mate acquisition when compared to young smaller males, relating to a better reproductive success (Isaac 2005). Therefore, reproductive success of males is dictated not only by the effective production of semen but also by its physical dominance over other males and the ability to attract females benefited by an increased body size, leading to a high energetic cost (Bronson 1985). Thus, competition is

avored by size in many species, particularly among males.

### Silver Spoon and Maternal Effects

Each individual has its own life history trajectory that starts during his or her development. Thus, variation between individuals is expected. For instance, when a favorable environment during development brings positive traits in the adulthood, it is called the silver spoon effect (Grafen 1988). Such an effect has been detected in tree squirrels *Sciurus vulgaris*, operating by means of younglings growing during good seed-crops seasons presenting an advantage when compared to others (Wauters and Dhont 1995). However, when analyzed in a different species, the root vole *Microtus oeconomus*, this effect was not as pronounced, perhaps because there is a very specific and sensitive period for this effect to be important, for example, during lactation (Rémy et al. 2011).

Another and a more familiar effect is a trans-generational one called the maternal effect (Kempthorne 1969). The phenotype of the mother or the environment she experienced affects the phenotype of her offspring, as in larger mothers give birth to larger babies. Degus *Octodon degus* present an interesting example. Degus mothers that had increased androgens (testosterone) levels during the prenatal period had masculinized offspring. Masculinized females, although more aggressive and sometimes less attractive to males, produce larger litters and heavier individual pups (Correa et al. 2016). It is important to note that the uterine environment is decisive for the development and changes of many life history traits.

### Geographic Variation

Abiotic and biotic variables are closely related to geographic locality. Thus, when considering geographic variation, it is difficult to separate variation related to climate/resource from variation related to geographic locality. The parameters that vary across regions are photoperiod, food, rainfall, and temperature.

Regardless, an important requirement for studying geographic variation is a wide distribution, similar to the genus *Peromyscus* in North America (Bronson 1985). At higher latitudes, *Peromyscus* exhibit short breeding seasons (2 or 3 months), and

they produce only one litter per year. At mid-latitudes, their breeding season is longer, from 5 to 7 months, and several litters are produced in the same year. At low latitudes, they breed mostly year-round, except for the highly seasonal habitats regarding rainfall patterns.

Altitude also influences life history traits. Alpine yellow-bellied marmot (*Marmota flaviventris*) females do not breed in successive years at 3,400 m high, while females at 2,900 m breed every year (Johns and Armitage 1979).

Differences in parental care related to geography have been identified in prairie voles and meadow voles (Wolff and Sherman 2007). Prairie vole populations located at two different places (Illinois and Kansas, USA) had different levels of parental responsiveness. Differences in parental care were considered to be a result of resource abundance (Illinois is richer). As for meadow voles, males of different origins also had different levels of paternal care. Males from Canada, with harsher environmental conditions, cared more for the pups when compared to males from the United States.

### Yearly Variation

General yearly fluctuation is expected for rodents. Some populations will show periods of high abundance alternating with periods with near-zero abundance. Lemmings are known for presenting cyclic and fluctuating populations (Boonstra 1994). In the Neotropics, many rodents go population booms/bursts, what has been called “ratada,” a more intense but less rhythmic population fluctuation.

Booms/bursts and “ratadas” are commonly reported throughout the world. Abnormal rainfall or higher primary production may trigger these population outbreaks by facilitating out-of-phase breeding periods. Ratadas have been described for *Oligoryzomys longicaudatus*, *Abrothrix longipilis*, *Rattus argentiventer*, and *Wiedomys pyrrhorhinos* in South America and in Indonesia (Singleton et al. 2001; Pearson 2002; Sobral and Oliveira 2014). The mast seeding of bamboo is a common explanation for many of the ratada events, especially because some bamboo species breed every dozens of years, augmenting the environment capacity support.

### Iteroparity Versus Semelparity

Other interesting strategies regard how many breeding opportunities an animal has throughout its lifetime. Iteroparity can be defined as the ability to reproduce more than once in your lifetime, while semelparity is like salmon, in which they breed only once and then die (Barry et al. 2001). The arctic ground squirrel *Urocitellus parryii* presents a drastic life history strategy, considered as “partially semelparous.” By hibernating necessarily for 8 months, breeding opportunities are restricted to a short period of the year. Competition for mating opportunities is high so that the energetic requirements of breeding lead to the disappearance of 48% of males after their first (and only) breeding season (Edwards et al. 2016).

Because multiple matings are commonly observed in rodents, amusing strategies exist to cope with this competition. As seen in Cape ground squirrels, males are exposed to a high sperm competition because females copulate with various males. However, prairie dog species (*Cynomys* spp.) present a distinct behavior in which males sequester a fertile female, blocking the entrance and preventing her from leaving as well as other males from entering. Interestingly, male maras urinate on fertile females, which researchers have proposed to act as a repellent to other males.

### The r-K and the Fast-Slow Continuums

Mammalian life history strategy is frequently visualized as an r-K continuum (Pianka 1970). In theory, at the r-endpoint animals experience environments with no competition, so that the optimal strategy is to focus on producing as much offspring as possible, even at the expense of caring less for each individual young. Thus, r-selected organisms are marked by high productivity. As for the K-endpoint, animals experience environments with high competition. Therefore, the optimal strategy is to produce fewer young but focus on caring more for each one – a young of high quality. Unlike the r-selected organisms, the K-selected mothers and fathers direct energy on producing just enough offspring to replace them.

There is body literature relating the r-K continuum with adult body mass among mammals.

However, when the influence of body size is removed (statistically speaking), life history traits continuum is termed as fast-slow continuum (Promislow and Harvey 1990). This continuum reflects mainly the fertility related to age at maturity, but also high reproductive rate, early maturity, and low survival. Both the r-K and the fast-slow continuums are commonly known as “mouse-elephant” differences.

Rodents are usually considered as r-selected organisms that produce large litters with brief parental care. They usually live shorter lives, and, when compared to other mammalian species, they are placed at the fast end. However, when comparison comprises only Rodentia, representatives we can still observe differences (Dobson and Oli 2007). For instance, the capybara attains sexual maturity at an early age, gives birth to a small litter with precocial young after a long gestation. This strategy is very different than that of elephants (1 young produced every few years and sexual maturity reached at 15 years), so capybaras can be considered as r-selected and fast-living if the other endpoint is an elephant. However, when compared to a smaller relative, the house mouse, capybaras can be considered as a K-selected slow-living animal. Hence, both r-K and fast-slow continuums are not universal and depends on the scale we are dealing with.

### Conclusions

Rodents comprise nearly half of the mammalian species and inhabit all continents and environments (except Antarctica). Although the vast majority is small-bodied (<5 kg) species, there are exceptions to the rule, such as the capybaras, the largest rodent that may reach up to 66 kg. One almost universal trait among rodents is their early maturation, but they generally share other life history traits, like high metabolic rate, short gestation length, weaning and sexual maturity attained at early age, large litters produced at short intervals with brief parental care, fast growth, high mortality, and short life span, characteristics that identify them as r-selected or fast-living creatures. However species deviate from

this pattern. For instance, Sciuromorpha group representatives are mainly solitary, but marmots and prairie dogs, included in the same group, are not. As for litter size, most groups have large litters, such as the lab rat (Myomorpha) that can give birth up to 20 pups. However, other groups, like the Caviomorpha, do not have such large litters. Moreover, although many rodents display brief maternal care and lack male parental care, muskrats do have direct male parental care, and naked mole-rats rely on the colony for taking care of newborns. Despite these differences, life history variation follows similar trends. The most common sources of variation are age and size (endogenous) and environment (exogenous), and rodents are particularly sensitive to environmental variation. Finally, rodents are generally considered as r-selected organisms with fast life history strategies when compared with other mammalian orders. Yet, there are differences within the order Rodentia, with large and long-lived rodents producing small litter with precocial young after a long gestation placed at the slow end and the small short-lived ones at the fast endpoint.

## Synonyms

Rodent locomotion; Rodent gaits

## Definition:

Movement used by members of the order Rodentia to transverse their environment.

The Rodentia encompasses a diverse family of species; by size, the order ranges from the Baluchistan pygmy jerboa at 3.75 grams and 4.4 centimeter body length to the capybara at 66 kilograms and 134 centimeter body length. Accordingly, species have ranging habitat preferences from deserts to urban environments. While Rodentia

includes many common pests, many of these species play important ecological roles including being keystone species in some ecosystems (Martínez-Estévez et al. 2013). For example, the prairie dog maintains soil properties, creates new islands of habitat, and improves nutritional quality of forage (Martínez-Estévez et al. 2013). Species such as the squirrel, scaly-tailed squirrel, woodrat, and chipmunk inhabit arboreal environments (Essner 2007; Karantanis et al. 2017), while gophers, mole rats, groundhogs, and prairie dogs spend most of their time underground in tunnel systems (Martínez-Estévez et al. 2013). The earless water rat, beaver, and muskrat are semi-aquatic (Casanovas-Vilar et al. 2008). The house mouse and brown rat are commonly found cohabitating with humans in urban centers including cities, towns, and farms (Langton et al. 2001). The ecological diversity of the order has resulted in a range of locomotor adaptations and species are known to utilize terrestrial quadrupedal and hopping gaits, arboreal locomotion, gliding, and even swimming (Fig. 1). This chapter introduces the varying locomotor modes observed within the Rodentia.

## Terrestrial Locomotion

Quadrupedal walking and running represent the most common form of terrestrial locomotion in rodents. At moderate paces, rodents tend to have symmetrical gaits. However, at higher velocities, their gaits can be asymmetrical (Karananis et al. 2017). Lateral sequence diagonal couplet gaits tend to be the most common limb sequence observed in terrestrial rodents (Fig. 2). A lateral-sequence gait is one in which each hindlimb footfall is followed by an ipsilateral forelimb footfall (i.e., right hindlimb, right forelimb, left hindlimb, left forelimb). Commonly, during walking gaits, the forelimbs and hindlimbs are traveling together as a slightly asynchronous couplet. When the ipsilateral forelimbs and hindlimbs are traveling together, this is referred to as a lateral couplet; when the contralateral forelimbs and hindlimbs are traveling together, this is referred to as a diagonal couplet. Very rarely do the limbs move

**Rodentia Locomotion, Fig. 1** Rodents show a range of locomotor modes, such as (a) hopping in kangaroo rats (*Dipodomys sp.*), (b) arboreal climbing in gray squirrels (*Sciurus carolinensis*), (c) gliding in flying squirrels (*Glaucomys sp.*), and (d) quadrupedal walking in mice (*Mus musculus*). **Rodentia Locomotion, Fig. 2** Hildebrand plot showing the relationship between hindlimb duty factor (%) and Phase (%) for fourteen species of rodent

together in perfect synchrony. The lateral sequence diagonal couplet gait is argued to be quite stable due to the generally low proportion of the stride spent as a unilateral bipod (~22%), and the relatively high proportion of the stride spent as a diagonal bipod (only two contralateral limbs in contact with the support) and large tripod (three widely splayed limbs in contact with the support).

While the above definitions of gait are useful for classifying rodents compared to mammals, the utility of such definitions is questionable in species that primarily rely on intermittent locomotion (also known as stop-and-go locomotion). Intermittent locomotion is when the force an animal exerts to move itself through space is applied discontinuously and the pauses last longer than a single cycle of limb movement (Gleeson and Hancock 2001). A terrestrial organism engaged in intermittent locomotion typically comes to a

complete stop during the nonpowered phase. Intermittent locomotion in the rodents is most common during foraging and habitat assessment, but the reader should be aware that rodents can adopt longer cyclical locomotor bouts during certain behaviors (e.g., predator escape). Studies on intermittent locomotion have been limited due to the noncyclical nature of the behavior and high variability between locomotor bouts. For example, gray squirrels approaching a food source away from forest cover made 22 pauses per minute and spent 35% of their time paused, while those carrying a nut to a site for hoarding in forest cover made 10 pauses per minute with 14% of their time paused (Gleeson and Hancock 2001; Kramer and McLaughlin 2001).

One major concern for rodents, and small-sized animals in general, is energetic expenditure during locomotion (Reilly et al. 2007). In fact, some of the highest daily locomotor costs have been observed in rodents [i.e., the golden-mantled ground squirrels (*Spermophilus saturates*) expend ~13% of total daily energy expenditure devoted to movement; Kenagy and Hoyt 1989]. Intermittent locomotion of rodents may amplify these concerns as this stop-and-start movement pattern entails more acceleration, more deceleration, and a higher speed. Both acceleration and active deceleration require energy expenditure. Moving at higher speeds may also require more energy expenditure per unit distance. Therefore, intermittent locomotion is expected to increase the energetic costs of moving over those of continuous locomotion under many circumstances (Gleeson and Hancock 2001). However, intermittent locomotion may permit some recovery from fatigue and pausing may result in an overall greater distance travelled (Kramer and McLaughlin 2001).

Bipedal hopping is a specialized form of terrestrial locomotion described as a sustained saltatory motion in which the hindlimbs contact the ground simultaneously without the use of the forelimbs (McGowan and Collins 2018). Bipedal hopping is commonly noted to have originated from desert regions. It has been hypothesized that bipedal hopping is advantageous for animals in desert environments because it confers locomotor efficiency for access to scarce water resources

(McGowan and Collins 2018). Other hypothesized advantages of bipedal hopping include greater forelimb availability for use in activities like foraging (McGowan and Collins 2018).

Hopping has been shown to be energetically favorable in Fawn hopping mice (*Notomys cervinus*) (Dawson 1976). Energy consumption increases with stride frequency until faster gaits are achieved. In faster gaits, energy consumption continues to rise despite little changes in stride frequency (Dawson 1976). This energy expenditure is observed as locomotion changes from normal gait to hopping, with increased hopping strides at higher speeds (Dawson 1976). Consequently, Fawn hopping mice have markedly lower energy costs at faster locomotor speeds than quadrupeds of similar size (Dawson 1976).

Hopping rodent locomotor capabilities have directly influenced research into tissue engineering. Kangaroo rat (*Dipodomys sp.*) tendon properties are unexpectedly strong and tough. Accordingly, Javidi et al. (2019) proposed that these tissues could serve as a model for improving engineered tendon replacements. Javidi et al. (2019) observed that the tendons of kangaroo rat locomotor muscles have failure loads (a marker for how much deformity a material can bear before breaking) 45–49% larger than those of red kangaroos. Despite their small size, kangaroo rats can generate significant muscle stresses typically observed in much larger animals like red kangaroos.

## Arboreal Locomotion

The exploitation of an arboreal environment provides access to additional resources and minimizes risk from terrestrial predators. However, the diversity of available arboreal substrates (i.e., variable size, inclination, length, fragility, etc.) presents a demanding, discontinuous, and unpredictable three-dimensional environment that imposes a range of biomechanical challenges to arboreal rodents. As such, arboreal mammals have evolved a range of anatomical and biomechanical adaptations that have allowed them to navigate in trees safely and effectively (Granatosky et al. 2019; Karantanis et al. 2017).

In an arboreal context, gait patterns may serve as a behavioral mechanism to enhance stability and safety (Granatosky et al. 2019). These gaits can be either symmetrical, when the left and right limbs of a pair alternate, or asymmetrical, when the left and right limbs move more synchronously. Diagonal-sequence gaits [hindlimb footfall is followed by a contralateral forelimb footfall (i.e., right hindlimb, right forelimb, left hindlimb, left forelimb)] contribute to dynamic stability in arboreal substrate navigation and reduce the periods of the stride where the limbs are arranged as unilateral bipod. In contrast, lateral sequence gaits may be functionally linked to static stability in substrate navigation and maximize the proportion of the stride where the limbs are positioned as a wide polygon of support. During arboreal locomotion, duty factor usually decreases on larger substrates (i.e., longer swing phase) along with an increase in the frequency of asymmetrical gaits (Granatosky et al. 2019; Karantanis et al. 2017).

Asymmetrical gaits, including gallops, half-bounds, and bounds, are commonly used by mammals at high speeds and frequently include a whole-body aerial phase (Granatosky 2018; Hildebrand 1980). It has been proposed that asymmetrical gaits may be preferable over symmetrical gaits during faster locomotion as they confer a reduction in the peak reaction forces, decrease the strain on the musculoskeletal system, and may optimize metabolic costs, at least at the trot-gallop transition (Hoyt and Taylor 1981). For small arboreal rodents, asymmetrical gaits further confer advantages in stability by limiting center of mass oscillations. However, data on the use of asymmetrical gaits during arboreal locomotion in rodents is limited (Karananis et al. 2017).

Beyond categorical gait sequences, arboreal stability is also influenced by speed, which is a function of stride frequency and stride length (Granatosky et al. 2019; Karantanis et al. 2017). Arboreal neotropical rodents exhibit overall higher velocities than terrestrial species as a mechanism to maintain dynamic stability (Karananis et al. 2017). Increased velocity during arboreal locomotion can be achieved either by

increasing stride frequency, and decreasing stride length, by increasing primarily stride frequency and, at a lesser rate, stride length, or by reducing stride frequency while increasing stride length. Increasing velocity through increased stride length is often encountered in medium-sized and larger arboreal mammals. This enhances safety during arboreal locomotion as the longer reach of the forelimbs minimizes branch sway. In contrast, increasing velocity by stride frequency may be better suited for smaller arboreal mammals, which are subject to insignificant branch sway, as it decreases body oscillations at limb touch-downs (Granatosky et al. 2019; Karantanis et al. 2017).

Forelimb and hindlimb kinematics of arboreal locomotion have been primarily limited to studies of medium/large-bodied primates using symmetrical gaits. Thus, the applicability of “general kinematic patterns” gleaned from these previous works may be limited regarding joint movements of the rodents. However, research on the arboreal locomotion of *Rattus norvegicus* by Schmidt and Fischer (2010) did reveal some commonalities with primates that might indicate shared behavioral adaptations caused by the biomechanical constraints of arboreal locomotion. Specifically, arboreal animals tend to show increased elbow and knee flexion throughout stance phase compared to terrestrial counterparts. Increased flexion at these joints is thought to lower peak vertical forces during arboreal locomotion, which in turn reduces joint reaction forces at mobile, but unstable, limb joints. Furthermore, shoulder and hip excursion tends to be greater in species that commonly utilize arboreal locomotion. Greater excursion at these joints arguably increases stride length, which in turn reduces stride frequency and therefore substrate oscillations. These joint movements tend to become exaggerated as substrate size becomes smaller relative to the body size of the animal. However, such generalities are not without criticism. Schmidt (2005), using a comparative approach across a range of small mammals, demonstrated that hindlimb kinematics change little in response to substrate (i.e., arboreal versus terrestrial), but instead are size dependent. As such, it may be the case that forelimb

kinematics are affected more by moving on thin arboreal substrates compared to hindlimb movements. It should be noted that these patterns may apply only to symmetrical gaits and are not relevant when animals use asymmetrical gaits, including gallops, half-bounds, and bounds.

Gliding is another mode of arboreal locomotion used by some rodents [e.g., the northern flying squirrel (*Glaucomys sabrinus*), common giant flying squirrel (*Petaurista petaurista*), and the Anomaluridae]. During gliding, animals increase their body surface area to enhance drag as they parachute down from elevated arboreal substrates. Anatomically, *Glaucomys* species exhibit elongated lumbar vertebrae and forearms (Granatosky et al. 2014; Thorington and Santana 2007). These anatomical features allow for enhanced drag as the body's surface area is increasingly in contact with air. In gliding animals, the energetic cost of quadrupedal locomotion increased as their morphology evolved to better align with gliding arboreal locomotion (Flaherty et al. 2010). However, gliding results in significant energy savings and reduced total travel time as the animal is moving in-between foraging sites (Flaherty et al. 2010).

## Aquatic Locomotion

There are Rodentia species, such as the members of *Castoridae*, that exhibit mixed terrestrial and aquatic locomotion, but with preference towards aquatic environments (Casanovas-Vilar et al. 2008). Morphological features specific to this genus include externally rotated femurs with a broad diaphysis and tibiae with lateral curvature that result in lateral deviation of the feet. In contrast to other Rodentia species, members of the *Castoridae* family also have knee and hip joints that contain more connective tissue, thus making these joints more fixed. These features, combined with the presence of large adductor muscles and intrinsic foot muscles, make the rapid alternating sequence of foot dorsiflexion and plantarflexion more suitable for propulsion in aquatic environments (Carlson and Welker 1976).

## Conclusion

Rodentia consists of a wide range of species occupying varied habitats and disparate locomotor behaviors. These locomotor modes developed based on survival needs, lifestyle, and energetic favorability. Modes of locomotion in Rodentia include terrestrial and arboreal quadrupedalism, gliding, hopping, and swimming. Studying these different locomotor styles in rodents provides further insight into evolutionary characteristics that allow these species to survive in their environments and enlightens future innovations.

## Rodentia Morphology

Mystera M. Samuelson

Animal Behavior Core, Department of  
Comparative Medicine, The University of  
Nebraska Medical Center, Omaha, NE, USA

### Introduction

The order *Rodentia* includes over half of all modern mammals including over 2,200 species divided into 33 families (Yarto-Jaramillo 2015). This entry will discuss, generally, the unique morphological adaptations of rodents, with a particular focus on rats and mice due to their common usage in psychological and biomedical research.

### Cardiovascular System

As mammals, rodents possess a four-chambered heart, a dominant left ventricle, and thinner right ventricle. Heart rate varies depending upon species (e.g., mouse ~350–700 beats/min and rats ~300–400 beats/min). The rodent heart is spherical to oval in shape and lacks a distinct intraventricular groove (Beutow and Laflamme 2018).

### Dentition

Mammalian dental morphology provides clues for the animals' diets and habitat, thus providing insight into the species' behavioral ecology (Helder Gomes et al. 2013; Renaud et al. 2005). One notable morphological adaptation present in all rodents is the characteristic open-rooted and rapidly growing incisors – which require individuals to constantly chew on dense material to prevent overgrowth (Grant 2014; Yarto-Jaramillo 2015). All rodents have monophyodont dentition, meaning that all teeth are permanent and will not be replaced if extracted. Rodents also possess a large diastema between the incisors and molars (Yarto-Jaramillo 2015). In guinea pigs and

chinchillas, however, all teeth are open-rooted and grow throughout the lifespan. Like the incisors, the animals' natural diet of dense vegetation controls this growth, preventing malocclusion. If unchecked, malocclusions can be both painful and deadly, leading to starvation as well as bone and soft tissue damage (Grant 2014). Rodent enamel is unevenly distributed along the labial surface of teeth (Yarto-Jaramillo 2015) and is typically yellow due to iron deposits in the enamel (Treuting et al. 2018).

### Excretory and Gastrointestinal Systems

All rodents are monogastric, possessing a simple stomach with glandular portions. Structural deviations in the structure and function of the rodent gastrointestinal system directly reflect the animals' diet. Strict herbivores, such as muskrats, have glandular tissue throughout the entire stomach, a large cecum, and an elongated colon to maximize nutrient absorption. However, in carnivorous species such as the water rat, approximately 70% of the stomach is covered in glandular tissue. Rats are unique in that they do not possess a gall bladder (Yarto-Jaramillo 2015). However, the rat common bile duct demonstrates ciliary adaptations which allow it to function in a manner similar to the rabbit gall bladder in terms of permeability (Smith and Boyer 1982). The presence of a gallbladder, in rodents, appears to be reliant on the presence of only one or two mutations. This, coupled with varying selection pressure in the wild, has resulted in considerable variation across rodentia. That is, many species present with, and without, a gallbladder (Geise et al. 2004; Kruepunga et al. 2019).

Unlike humans, rodents possess a lobated liver which contains four lobes: the ventromedial lobe, right and left dorsolateral lobes, and the caudate lobe. Additional lobes tend to develop in order to form a proportionately larger liver, increasing the general number of lobes rather than the overall lobular size. Regardless of the number of lobes present, the internal architecture of the liver remains the same (Kruepunga et al. 2019).

## Reproductive System

Famous for their ability to procreate, the rodent reproductive system is efficient and well-studied. Many small rodents are spontaneous ovulators. However, in many species the vagina is opened only when the animal is in heat, during parturition, or has an infection in the reproductive tract (Yarto-Jaramillo 2015). Male murine rodents have been found to have a near isometric relationship between body size and testes size, although the size of spermatozoa was not found to be related to either body or testes size (Breed and Taylor 2000).

## Respiratory System

The rodent trachea is C-shaped and contains between 15 and 25 (depending upon species) incomplete cartilaginous rings. In rodents, the right lung contains four lobes (cranial, caudal, middle, and accessory) while the left contains only one. Mice and rats both have two extrapulmonary bronchi (conducting airways with cartilage). These extrapulmonary bronchi subdivide to form the intrapulmonary bronchi, supplying air throughout the lungs. These intrapulmonary bronchioles lack both cartilage and submucosal glands. Instead, nonciliated cells are predominantly responsible for rodent airway secretions. Rodent airways branch in what is known as an asynchronous, monopodial branching pattern, meaning that smaller branches project from larger branches of the airway. Unlike humans, rodents lack well-defined bronchioles (Meyerholz et al. 2018).

## Neurological System

The structure and function of the rodent brain reflects their unique sensory and cognitive capabilities, and by extension their Umwelt. The rodent brain lacks the sulci and gyri known to human brain anatomists to provide external landmarks. Unsurprisingly, the rodent olfactory bulb is quite large in comparison to humans and thus

reflects their advanced sense of smell. The parafloccular lobule of the cerebellum is much larger in comparison to humans, while the cranial lobule has less lateral spread than humans. Similarly, the human middle lobe is proportionately larger in humans. These differences in cerebellar structure reflect the rodent's need to establish and maintain balance, processing visual and vestibular information to achieve this aim (Snyder et al. 2018).

## Inbred Rodent Strains

Understanding the biology and behavior of the order Rodentia can be a daunting undertaking due to the size of the order and the inter- and intraspecies variation represented therein. However, this endeavor is further complicated by the development of inbred rodent strains used in biomedical research. For example, the structure of mouse strains C57BL/6 and BALB/c present with vastly different tracheal structures (Meyerholz et al. 2018). Thus, laboratory studies must include a thorough evaluation of the baseline anatomy, morphology, and behavior of rodent strains prior to experimental manipulation.

## Discussion

The morphological characteristics described here are critical for the proper phylogeny and anatomical evaluation of the many rodent species (Stein 2000). Rodents, of course, are not only found throughout nearly all terrestrial ecosystems, but are also employed as a model in a great number of biomedical tests, and thus, a detailed understanding of their anatomy, ethology, morphology, and evolutionary history is critical to the development of proper experimental design and scientific advancement.

## Synonyms

Acquisition of knowledge about spatial location; Spatial learning

## Definition

Rodentia navigation refers to how rodents find their way about (i.e., to find food or water, or to return home), to the many strategies and mechanisms underlying spatially guided behavior. Rodents have a varied range of strategies, some innate and others learned, that help them to navigate, and when faced with a specific spatial task, the one they choose will depend both on their sensorial capacities and on the nature of the stimuli that are available (for reviews see Rodrigo 2002; Tommasi et al. 2012).

## Background

Rodents can use different navigational strategies to locate a goal. Moreover, they can use a given strategy in a specific situation and under different conditions, use another one. The ability to find their way round their world is seen as of critical adaptive significance. Rodents can navigate using

information based on conspecifics (social influences), on their own movement (i.e., dead reckoning or path integration), on a single beacon or landmark, on multiple landmarks (which includes geometric encoding), or they can navigate using information based on the relationship of multiple landmarks (i.e., which is often called “a cognitive map”). Rodents can also use a visual matching strategy. In the last decades, there has been a great interest in discovering the navigational strategies they use, the conditions for using each strategy, as well as understanding the neural mechanisms of navigation. The most interesting results have been obtained with gerbils and with rats. Rodents are usually considered to be burrowing animals. They use their burrows for different purposes (e.g., to store food and to escape from perceived threats). A number of behavioral examples will be reviewed below.

### **Social Influences on Navigation while Foraging. A Case of Episodic Memory?**

Learning from other conspecifics is important for many animals and the spatial domain is not an exception. Rats begin their search for food from a central point, their burrow. This characteristic makes the exchange of information with their conspecifics crucial in order to determine where food is located.

In social interaction, the information is transmitted through olfactory cues. Moreover, rats have the ability to detect if their conspecifics have eaten recently as well as what they have eaten, which can lead to a preference for a particular food in a specific spatial location. Therefore, social interaction can facilitate where food is located (Galef 1988).

Social influences while searching for hidden food has been much studied recently using different arenas as well as the radial maze, where choices are determined by spatial location (Brown 2011). For example, a recent study by Bisbing et al. (2015) examined the conditions under which the spatial choices of rats searching for food were influenced by the choices made by other model rats. The results showed that the social influence could be very strong under at least some conditions; they support the claim

that the information that an animal acquires directly from its own experience with the environment (personal information) as well as the information provided by model rats (social information) are important. However, social information about the food location could influence spatial choices only when the social cues provided information that was not redundant with the information provided by other nonsocial cues. The clear implication is that the social cues and other kinds of stimuli seem to share the same or similar conditions, basic effects, and mechanisms. Both sources of information can be used in a flexible and adaptive way to guide choice decisions.

Are the previous examples a case of episodic memory, of memory based on conscious recollection? Could the rats remember the integrated “what,” “where,” and “when” information from specific past events? A very interesting approach to understand episodic memory in rats involves what is referred to as “source” memory (also called source monitoring). Source memory refers to memories about the conditions under which a memory was acquired (see Jonathon Crystal in the present issue).

### **Dead Reckoning or Path Integration**

Dead reckoning or path integration refers to the process by which animals keep track of their current position in relation to a known position by using internal vestibular and kinaesthetic information, that is, information based on their own movement. To do so, they continuously process information about changes in distance and direction at the different points of their path. For example, Mittelstaedt and Mittelstaedt (1982) placed mother gerbils and their pups inside a nest that was at the edge of a large circular arena. The pups were then caught and displaced to a hole in another part of the arena. They observed that the mother soon began to search for the pups and that as soon as she found them, picked each one up in her mouth, and went straight back to the nest. The gerbils performed equally well in conditions of total darkness and when the outward path had zigzags and detours. The best demonstration accomplished by dead reckoning comes from experiments on displacements. Mittelstaedt and

Mittelstaedt (1982) rotated the edge of the arena while the mother gerbil was in the hole, so that the nest was displaced. They observed that the mother gerbil returned to the place where the nest had been previously, demonstrating that the homing performance was not based on a cue present in the nest, but rather one based on path integration. They also observed that if the hole was rotated strongly while the mother and their pups were inside, the mother compensated for the rotation and headed straight back to the nest. However, if they rotated it or displaced it slowly sideways, the gerbil did not compensate and was disoriented. Similar results have also been obtained with golden hamsters. Although path integration can often be a very effective homing mechanism, it also has limitations. Both random and systematic errors often occur.

#### **Navigation Using a Single Beacon or Landmark**

Path integration tends to accumulate errors. Therefore, most rodents tend to use external landmarks to locate themselves or their goals. Preferably, they use proximal cues or beacons. Beacons are objects situated so near the goal that the animal simply has to perceive them in order to locate the goal. For example, Morris (1981) trained rats in a circular pool full of opaque water. Some of the rats could escape from the water by climbing up onto a black platform which was a centimeter above the level of the water. Under these conditions, the platform functioned as a beacon. The rats, good swimmers but not very fond of water, quickly learned to escape from the water by climbing onto the platform from different points of the pool. In the presence of a beacon, all the animals have to do is orient themselves and approach. For this kind of navigation, rodents only need to associate the stimulus-goal (or a stimulus that is close to the goal) with the reinforcer.

But landmarks are normally far away. Distal landmarks are fixed singular objects situated further away from a goal than a beacon is, but which are still close enough to provide some information about the distance to the goal. If they are asymmetrical, they can also provide directional information. Finding a goal (i.e., determining both

direction and distance) on the basis of landmarks is called “piloting” (Cheng and Spetch 1998). A very influential study was carried out by Collett et al. (1986), with female gerbils. The animals learned to dig for a sunflower seed buried in bedding, with a cylinder landmark placed at a fixed distance away. The gerbils learned to search in the correct location based on the landmark. To locate a goal based on a landmark, an animal has to perceive the distance and the direction of their position with respect to the landmark, to remember the distance between the landmark and the goal and its direction, and then to calculate the distance and direction from its position to the goal. The authors used a single symmetrical landmark in these experiments, which is not enough to pinpoint the location of a goal. Such a landmark only indicates the distance to the goal, but not the direction. Thus, the animals must have obtained directional information from another source. Given that the landmark was moved from trial to trial, but always at the same orientation with respect to the experimental enclosure, possibly the gerbils were able to obtain directional information from some other cues (like a door or a window). Moreover, Collett et al. (1986) carried out different tests in which they changed the size of a landmark and observed that these changes did not affect the place in which the gerbils searched for food. These results showed that gerbils do take into account the distance between the landmark and the goal, regardless of the landmark’s size.

#### **Navigation Using Information Based on Multiple Landmarks (Which Includes Geometric Encoding)**

In another experiment by Collett et al. (1986), it was shown that gerbils can use information about the relative position of several landmarks that maintained a constant relationship to a goal. Gerbils were trained in an arena, a sort of open field, to find hidden food in a place that maintained a fixed relationship with the position of two distinct and equidistant from the food landmarks. Following training (i.e., once they had learned to locate the food), a series of test trials were conducted. When one of the landmarks was removed, the gerbils searched in two locations whose directions

and distances corresponded to those between each of the landmarks and the goal during training. This suggests that the animals knew the direction and distance of the food from the landmarks, but that they did not know the identity of the landmarks. Each landmark was treated as if it could have been either of the two training landmarks. In another test, the distance between landmarks was doubled and the gerbils searched in two places defined by the direction and distance of the goal from each of the two training landmarks. These results show that the gerbils, at least the females, calculated the distance and direction of the food from each cue independently.

Cheng (1986) was the first author to present evidence that rats can use geometric information to locate a hidden goal. He trained male rats in a rectangular arena, where the two short walls of the box and one of the long walls were black, while the other long wall was white. In addition, distinctive visual patterns were placed in each of the box's corners, as well as other nongeometric cues, like different odors. Food was buried in one corner of the box, and the rats had to search for it. Although rats learned to search in the correct location for the food, they made frequent rotational errors searching in the corner diagonally across from the one where the food was hidden. The only characteristic that the target corner and the corner diagonal from it shared in common was having one long wall to the left and one short wall to the right, which implies that the information provided by the nongeometric sources of information to find the food location did not seem to be important. Cheng (see also Gallistel 1990) concluded that the rats used the geometrical framework of the box itself. Thus, what the rats learned was to search for food in the corner that had the long arm to the left and the short arm to the right. This would explain why the animals made rotational errors, since the corner diagonally opposite had the same properties. This experiment clearly shows that rats are sensitive to the geometrical relationships of a test environment. According to Cheng (1986) and Gallistel (1990), learning about geometric information (i.e., like the metric relations of distances and angles between a target place and the shape of an

apparatus) occurs in a specialized module, which is impenetrable to nongeometric information. However, Miller and Shettleworth (2007) have claimed that changes in the associative properties of the geometric cues are governed by the same principles that apply to more traditional stimuli. Following these authors, geometric and featural cues (or landmarks) are separate elements, so that, for example, each corner in a specific apparatus has its own combination of the two kinds of cues, which are learned simultaneously and can interact (i.e., therefore, blocking and overshadowing, cue competition designs, are expected to occur). Well-designed experiments and different authors have confirmed the two previous outcomes with male rats (for a review see Pearce 2009).

Interestingly, in a pioneering study by Williams et al. (1990) with geometric and nongeometric cues, in which males and females were employed, a surprising result was found. Williams et al. (1990) trained rats in a radial maze. After they had reached asymptotic performance, the rats were tested following various manipulations to the geometry of the room or to the landmarks. Provided the geometry of the room was unchanged, males' performance was unaffected by any change to the landmarks, but alteration of the geometry of the testing room disrupted their performance, even when the landmarks were still available for navigation. In contrast, females' performance was disrupted by rearrangement of the landmarks whether the geometry of the room was changed or not, although they were unaffected by the removal of the landmarks provided the geometry of the room was unchanged. A more recent study by Rodríguez et al. (2010) employed a different procedure to demonstrate rather similar effects. These results imply that a geometrical cue is more salient for males, while a landmark cue is more salient for females. A subsequent study by Rodríguez et al. (2011), where cue competition designs were used, confirmed this claim by showing that overshadowing is asymmetrical, both in males and in females. In males, geometry learning tends to overshadow landmark learning, but not vice versa; while in females, landmark learning tends to overshadow geometry learning, but not vice

versa. Moreover, these effects were not influenced by the females' estrus cycle.

Subsequent work with male rats suggests that the relative salience of both cues (geometry and landmark) seems to be able to completely reverse the previous results (Kosaki et al. 2013; Mesa et al. 2017). Taken together, the clear implication of the previous studies is that the rules that govern learning about the shape of the environment (Cheng 1986; Gallistel 1990), or its boundaries (Doeller and Burgess 2008), are not necessarily different to those that govern learning about landmarks. Moreover, the study by Williams et al. (1990) was the first to show that the failure to consider sex as a variable while studying spatial learning can undermine the reproducibility of research findings. Hopefully this should be corrected in the future.

The distribution of two or more landmarks in space also has geometrical properties. There is evidence that rats can learn both the geometrical properties defined by a configuration of landmarks as well as the landmarks' identity (Greene and Cook 1997). Greene and Cook (1997) trained male rats in a modified open field in which a fixed configuration formed by six different objects was presented to the animals. The rats searched for food, which was hidden in the upper part of several poles. Following acquisition, several test trials were conducted: with the same objects but in different positions, with different objects although occupying the same positions of the training objects, and with the training objects in their normal position. The results revealed that the number as well as the identity and the geometrical configuration formed by the objects were important factors when searching for food. Greene and Cook (1997) claimed that the animals learned the geometry formed by the objects and such learning included the objects identity as well as their specific position within the configuration they formed.

### Navigation Using Information Based on the Relationship of Multiple Landmarks. The Cognitive Map.

Tolman (1948) was the first author to propose that animals form sophisticated representations of

their environment and called this a cognitive map. Tolman conducted many maze experiments. We know that rats typically solve maze problems by learning to approach the place where the goal is. But how is this place defined? For example, how does a rat solve a T-maze problem? (see Fig. 1). Usually, food is placed in one of the two goal-boxes (GB+) and not in the other one (GB–), and the subject has to choose between one arm and the other at the choice point. This is a spatial discrimination task, and traditionally it has had two alternative explanations (i.e., place vs. response learning — classical conditioning vs. instrumental or operant conditioning). According to Tolman (1948), the rat learns to associate the correct goal-box, GB+, with food and the incorrect one, GB–, with its absence, so that after a certain number of trials it chooses the correct goal-box and avoids the incorrect one. On the other hand, according to Hull (1943), what the rat learns is to execute a certain response instead of another at the choice point, because the first one is followed by food while the second one is not. In both cases, it can be said that the animal has been

**Rodentia Navigation, Fig. 1** A schematic diagram of a T-maze. S-B = start-box, G-B+ and G-B– the rewarded and unrewarded goal-boxes. A, B, represent distinctive objects immediately adjacent to the goal-boxes, and C, D, E, and F are various landmarks (doors, windows, tables) in the room. The dotted start-box and arm at X represent a new location for the start of a test trial. (After Mackintosh 1983 –with permission)

conditioned, although for Tolman it is a case of classical conditioning, “place” conditioning (the rats learn associations between places and rewards), and for Hull it is a case of instrumental or operant conditioning, “response” conditioning (one could say that the rats learn associations between responses and rewards).

The results have been generally in favor of place learning (classical conditioning), even when the maze is rotated 180°. Tolman regarded conditioning as the acquisition of new knowledge about the world, instead of the acquisition of new responses or new reflexes. For him, the rats arrived at the correct goal-arm by using a cognitive map of the experimental room. But Tolman never explained the specific properties of the cognitive maps and gradually his theory lost credibility (O’Keefe and Nadel 1978).

In their very influential book, O’Keefe and Nadel (1978) claimed that rats can learn the correct trajectory to reach a goal in a maze in two ways. The main one, “true spatial learning,” they label locale learning (or the “hypothesis of the cognitive map”). A rat solving a problem by locale learning would form a cognitive map of the environment where the maze is located, and of the specific location of the rewarded goal-arm within that environment. A crucial feature of their account was that O’Keefe and Nadel (1978) consider that such learning is nonassociative, that it happens in an all-or-nothing way, and that it implies the formation and readjustment of a complete, global, representation of the environment in response to novelty. They also claimed that this kind of learning is highly flexible and that the hippocampus is the responsible cerebral structure. The second way to approach a goal they termed guidance learning. Learning by guidance implies approaching one specific cue or set of cues (a particular color, shape, odor or texture in the rewarded goal arm, for example, or a particular landmark or configuration of landmarks just behind the correct arm). Guidance learning was regarded as one form of taxon learning, the other being orientation learning, which is basically the same as Hull’s response learning. Guidance learning is associative and can be regarded as a form of Pavlovian conditioning that does not depend on the hippocampus. It is also

less flexible than true locale learning. These two strategies, locale and guidance, proposed by these authors to solve spatial tasks were traditionally understood as only one form of learning, place learning. However, O’Keefe and Nadel (1978) emphasized that locale and guidance strategies are two fundamentally different and independent forms of learning, each of them controlled by a different cerebral structure, and that only the taxon strategy, the guidance one, is controlled by associative laws. However, the following decades have demonstrated that their claims were not always correct. The two main ways of learning (locale and guidance strategies) are not independent, they interact. The clear implication is that knowledge about spatial location can be acquired in the same way as knowledge about other relations between events (for reviews see Chamizo 2003; Leising and Blaisdell 2009).

A critical test of a cognitive map (according to O’Keefe and Nadel’s proposal) would imply that experience of the route A-B-C-D not only would give knowledge of the direction and distance between A and B, B and C, and C and D, but would also be sufficient to allow deduction of the distance and direction from A to D in the absence of any experience of the direct route from one to the other. Very few experiments have shown this with rodents, although one by Roberts et al. (2007) is worth mentioning. In the study by Roberts et al. (2007), male rats were allowed to travel selected routes along the internal alleys of a cross-maze that led from one distinctive end box to another. A critical feature of this set of experiments was that only the internal geometry of the maze could be learned and used to travel between one end box and another. After an initial exploration phase, rats were given novel routes and shortcut tests that involved unknown peripheral alleys, that the rats had not used before. The animals chose the correct novel path or shortcut significantly above chance. These findings suggest that rats were able to compute novel routes and shortcuts within the maze on the basis of limited experience with the internal geometry of the maze. This study further shows that rats could link a place with a number of other locations when allowed to travel a single linking pathway.

### Navigation Using a Visual Matching Strategy.

An alternative account to the cognitive map hypothesis has shown that geometry can be less important than initially thought in rats. It refers to a snapshot (mental image) account of rat navigation, which is most important when animals are at a goal or near it (Cheung et al. 2008). According to Cheung et al. (2008), search behavior can be explained by assuming that the animals take a snapshot at the goal or near the goal. Then, on subsequent journeys to the goal, they will move in a way to minimize the difference between the memorized image and its current view. Cheung et al. (2008) proposed that mental snapshots are global in nature and involve a panoramic view of the entire environment; they include information about the spatial relationships between the different elements (i.e., distant from the goal landmarks or other featural cues) they contain. All that is required for an animal to be able to find a goal is that it can see at least a portion of the elements contained within a specific snapshot. This procedure based on the coincidence of images does not require an explicit learning of the landmarks or of the spatial geometry of the environment in which the goal is located. These cues are implicitly contained in the panoramic images taken by the animal and their relative salience will determine if the differences between the images perceived by an animal will be dominated by geometry or by features or landmarks. Subsequent research has revealed that mental snapshots can also refer to local cues (Gilroy and Pearce 2014).

The term “cognitive map” is nowadays used in many ways, so that depending on the author it can mean very different things. Following Mackintosh (2002) this term has lost explanatory value. What is needed instead is to ask what are the mechanisms underlying any particular example of spatially guided behavior. Many questions remain to be answered.

## Definition

Sensory systems are the physiological modalities by which individuals engage with the world. The major systems include audition, vestibular, gustation, olfaction, touch, and vision.

## Introduction

Across the order Rodentia are a variety of different mammals which use their sensory systems to interact with the world. These sensory systems vary in complexity and importance depending on the evolution and lifestyle of the animal. Rodents are diverse in both physical size and the environment in which they live. They are dependent on highly specialized and adapted sensory systems to engage with their environments and to survive.

Rodents live in wet and dry, hot and cold, aboveground and subterranean, and light and

dark environments. Across these environments, they live in either solitary conditions or large social groups (Feldhamer et al. 2015). In each of these contrasting environments and climates, different sensory systems assume the dominant role in environment navigation and survival, rendering others lesser or completely unused. A vast majority of research on physiology and function of sensory systems has been conducted on rodents due to this diversity, their small body sizes, short lifespans, and links between sensory systems and survival.

One relatively universal feature of the major sensory systems is the topographical organization of information in the environment being maintained within the sensory pathway. This is maintained by areas of higher and lower resolution on one feature of sensory objects that are being maintained within the system. For example, in the tactile system, touch for different parts of the body is relayed to adjacent locations in the brain. In the auditory system, frequency content is organized from low to high frequency in the cortex. In each sensory system, this cortical gradation starts at the receptor cells and is maintained along the entire pathway from receptor, to neurons, to the brain. The relationship between objects in the real world is maintained in stimulation of receptors and activation of the animal's cortex.

Each of the five major sensory systems (hearing, taste, smell, touch, and vision), as well as the vestibular system, will be discussed in this chapter. The range of acuity (or sensitivity) of these sensory systems differs systematically across different evolutionary contexts within the order Rodentia. The systems that prove the most biologically adaptive for each rodent species will have heightened acuity relative to other sensory systems. Some of the functional roles of the sensory systems include mate attraction, courtship, territory defense, and threat signals. These will also be discussed within the contexts of different major systems and in further detail in the Rodentia Communication chapter in this edition.

### **Audition**

The auditory system is the sensory system that is responsible for hearing. The auditory system in

all mammals, including rodents, is comprised of several different hearing structures located in the outer, middle, and inner ear. These structures function to receive sounds from the environment, amplify or suppress their intensity, and convert them into neural signals that can be interpreted in the brain. These major structures include the tympanic membrane, ossicles (malleus, incus, stapes), and the cochlea. The cochlea is a structure containing outer and inner hair cells and the basilar and tectorial membranes, which together convert sound into an electrical signals (action potentials) through mechanical movement. Action potentials are then transferred to the central auditory system, allowing for perception of frequency, duration, location, and meaning of sounds. Along the entire central auditory pathway, this information is coded tonotopically and organized in a low to high gradient, with low-frequency information in a different spatial location along the pathway than high-frequency information.

Methods of studying auditory function in rodents include observational studies of animals in the wild responding to sounds, as well as laboratory studies of the fine auditory resolution abilities of individual subjects. Skinner boxes, a behavioral apparatus used to study animal perception, can be used to train awake and behaving animals to respond only in the presence of a sound. Physiological tests, such as the auditory brainstem encephalographic response and distortion product otoacoustic emissions, can be conducted in anesthetized animals to estimate hearing abilities. These tasks measure the responses of the auditory system to sounds but are less sensitive than behavioral methods (Dent et al. 2018).

Audition is an important sensory system for rodents because signal transduction, such as in the case of communication signals, and receipt are not dependent on the presence of light in the environment. Across rodents, production of acoustic signals is diverse because individual animals are able to modulate the frequency range, duration, and/or temporal characteristics to change the meaning of their vocalizations. The auditory system needs to be tuned to these

changes for the system to be effective in communicative settings. The range of hearing sensitivity is represented by an audiogram, showing acuity in absolute thresholds across frequencies (see Dent et al. 2018 Fig. 4.1 Pg 74). In rodents, this range is highly variable, with some having much better high-frequency acuity (e.g., laboratory mice (*Mus musculus*) hearing spans between 1 and 100 kHz), while other rodents are more sensitive to lower frequencies (e.g., prairie dogs (*Cynomys*) hearing spans from 46 Hz to 26 kHz). The peak sensitivity of the species can also reflect the physical factors in the environment in which an animal lives and how that environment (e.g., high vegetation) affects signal propagation.

The auditory systems of rodents are tuned for detection of communication signals important for survival and reproduction. One classic example in rodents is the ability to detect an alarm call. California ground squirrels (*Otospermophilus beecheyi*) and Belding's ground squirrels (*Urociellus beldingi*) produce categorically distinct flee vocalizations for aerial predators and alerting vocalizations for terrestrial predators and conspecific intruders (Mateo 2010). The vocalizations that are emitted by squirrels must have specific features that make them easily discriminated from non-alarm signals and must also be able to be heard and understood by conspecifics in order to be effective. However, complex sound perception in rodents is not limited to interpreting alarm signals. Similar to categorical speech perception in humans, chinchillas (*Chinchilla chinchilla*) can be taught to discriminate a /d/ from a /b/ from a /g/ sound. Auditory signals also play an important role in rodent foraging behavior. Eastern gray squirrels (*Sciurus carolinensis*) eavesdrop on the non-alarm calls of nearby birds to know when to engage in food-seeking behaviors or to know when to engage in vigilance behaviors to a predator (Lilly et al. 2019). For a more complete review of Rodentia Communication, see *Kobrina and Burke* in this volume.

The auditory systems of rodents are highly tuned sensory systems that are important for communication, mate selection, play behavior, foraging, and survival. Loss of effective utility in this system, as in the case of anthropogenic

(human-caused) noise, can lead to detrimental consequences in any of these functional roles of this system.

## Vestibular

The vestibular system is the fundamental sixth sense that provides information about linear motion, acceleration, equilibrium, and balance (Bradbury and Vehrencamp 2011). Major organs of the vestibular system are the semicircular canals, the utricle, and the saccule. The three semicircular canals are important for detecting angular accelerations of the head, while the utricle and saccule are important for detection of linear velocity. Rodents utilize this system primarily for navigating their environment by integrating information about their own anatomy with the mode of locomotion and agility. This sensory system is crucial to maintaining normal function, but it is often ignored in humans until it becomes dysfunctional.

The vestibular system is evaluated in the laboratory based on a variety of different behavioral phenotypes. For example, animals with vestibular problems often engage in stereotypical circling behaviors, have difficulty correcting their body position when dropped, and struggle when being suspended in the air by their tail. The vestibular system can also be evaluated by studying the anatomical structures of several different species and comparing them to see whether there are evolutionary differences in the development of this system.

The vestibular system structurally has not changed much over evolutionary time, but slight differences in the conformation of the organs do occur across species. In several rodents the semicircular canals show evidence of differences in anatomical structure that is based on the primary mode of locomotion of the subject. For example, northern flying squirrels (*Glaucomys sabrinus*) glide for long distances in the air, which requires an intact, functional equilibrium system and involves balancing body weight at a constant velocity (Pfaff et al. 2015). Across *sciurids*, one of the major families of squirrels that is characterized by different types of locomotion, arboreal living tree squirrels (*Sciurinae*),

terrestrial living ground squirrels (*Xerinae*), and gliding squirrels (*Pteromyinae*) all show differences in the angle of the semicircular canals. These canals are typically located orthogonally, or in 90 degree angles to each other, so the width between them, diameter and lengths of the canals, and the angles of the planes can be characterized. Ground, flying, and gliding squirrels all have slightly different semicircular canal positioning and sensitivities, likely linked to the difference in major mode of locomotion and to avoid overstimulation.

The vestibulo-ocular pathway is an open-loop system in which a vestibular signal triggers compensatory eye movements (or a spontaneous nystagmus) to stabilize gaze in the absence of sensory feedback. Eye movements can be traced as a proxy to evaluate the efficiency of the vestibular system by characterizing the vestibulo-ocular reflex (VOR). In laboratory mice, the VORs have been measured in response to a vestibular sensory cue (e.g., being tilted into different angular planes corresponding to the semicircular canals). Often the compensatory mechanisms of the VOR are quantified to try to understand the level of vestibular impairment.

Vestibular functioning has been evaluated in laboratory rats as it relates to their gravity perception (Jamon 2014). A tail-lift reflex and an air-righting reflex are two types of antigravity reflexes regularly assessed in lab rats, as well as lab mice. The tail-lift reflex is where rodents are lifted by their tail, and the amount of time it takes to right their body position, as well as the angle of their body in space, can be measured. The air-righting reflex involves dropping the rodent from a suspended height in the air and seeing if it can correct its body position before landing on a padded platform. In subjects that experience a vestibulo-spinal deficit, there are usually gross alterations in spontaneous motor activity and motor reflexes that facilitate the identification of animals suffering from vestibular problems. These problems can then be quantified by measures like the amount of time it takes an animal to correct its body position in space.

The vestibular system is very important to avoiding predation. Because rodents are prey

species, small changes in their vestibular function could be the difference between effectively fleeing a dangerous situation and being captured and killed by a predator.

## Gustation

The gustatory sensory system is responsible for the perception of taste. Rodent gustation has been studied in the context of their food acquisition and to understand the specifics of how mammalian taste receptors work. The major sensory organs of the gustatory system include the tongue, papillae, and salivary proteins. The process of digestion begins in the animal's mouth, where food is pushed around by the tongue, crushed with teeth, and moistened with saliva. Salivary proteins begin the process of digestion of food within the animal's mouth. The salivary proteins differ based on the main dietary choices that animal makes and can play a critical role in future food preferences. On the surface of the tongue are papillae, which are special structures, most of which contain taste buds. Taste buds are sensory organs responsible for sending information about the taste and type of food an animal consumes to the cortex. In rats (*Rattus norvegicus*), the gustatory cortex has been mapped out indicating that there are distinctive spatial patterns with some overlap in the four classic taste qualities of salty, sweet, bitter, and sour foods (Accolla et al. 2007).

Taste is an important sense because discrimination between nutritious and toxic sources of food can be the difference between life and death. Wild rodents living in highly populous urban environments often face this type of risk and need to be sensitive to gustatory, olfactory, and visual cues in potential food sources to survive. For reproduction, the ability to pick out nutritious foods is correlated with larger body sizes and a better ability to produce strong vocalizations, leading to an increased likelihood to be selected for mating (Bradbury and Vehrencamp 2011). Whether all rodents' taste receptors can discriminate between all of the different major types of tastes is unclear, yet there does appear to be spatially separate cortical representation for these different tastes in some rodents (Accolla et al. 2007). One way to examine this

behaviorally is using a flavor avoidance learning task. Norway rats (*Rattus norvegicus*) and golden hamsters (*Mesocricetus auratus*) categorize different tastants into the four major groups of sweet, sour, salty, and bitter. Their inherent preference for, or avoidance of, particular tastants can be exploited to encourage them to ingest particular food sources based on their nutritional value. This is also a useful cue for them to attend to in order to avoid potential chemicals. For example, differences in dietary choices are one factor responsible for why pocket gophers (*Thomomys umbrinus*) are more tolerant of bitter-tasting foods than squirrels, chipmunks, and most laboratory mice and rats (Hani et al. 1998).

Taste has been studied in the lab using behavioral and physiological methods. In an operant task, rodent feeding behavior can be assessed by quantifying the number, preference, and size of feeding events for different types of diets (e.g., bitter versus sweet) (Tordoff 2007). In the wild, bitterness is usually a cue to toxicity, but this association must be learned. Saliva can also be collected and evaluated to see whether a physiological change occurs in response to dietary choices. Preference studies can reveal how a subject may respond to different dietary options and whether there are specific food choices a subject would rather consume than others (or whether one food choice is particularly aversive). Flavor avoidance learning is one type of behavioral test that has been conducted to show how rodents are able to behaviorally categorize different types of tastes (Parker 2014).

In the laboratory, taste preferences have been explored in rats to show that they prefer sweet sucrose solutions to bitter quinine solutions (Torregrossa et al. 2015). This preference has also been shown in golden hamsters (*Mesocricetus auratus*), with differences across the sexes linked to progesterone levels (Zucker et al. 1972). The preference for sweet solutions is strong in laboratory mice (CBA/CaJ) that are more motivated to engage in a behavioral task when given a chocolate Ensure<sup>®</sup> protein shake as reinforcement than any other flavor of Ensure<sup>®</sup> or water (Radziwon et al. 2009).

Taste is one of the most crucial sensory systems for survival because finding appetitive food sources and discriminating them from aversive food sources can be the difference between ingesting poisonous/toxic or nutritious sources of food.

## Olfaction

The olfactory system is the sensory system that is responsible for the sense of smell. In rodents, the olfactory system is composed of two separate systems: the main olfactory system and the vomeronasal system (VNS; also known as the accessory olfactory system). The main olfactory system processes chemosignals in a variety of behaviors such as mating, feeding, predation, and aggression, while the VNS is used for pheromone-based communication with conspecifics. Arguably, the olfactory system is the most critical sensory system for survival in rodents because olfactory cues can have effects on mood, behavior, hormonal status, or sexual arousal of the recipient. In addition to these effects, rodents are obligate nasal breathers, where the upper air passage meets the slightly elevated epiglottis in the nasopharyngeal areas, thereby not sharing a common pathway with food in the oropharynx (Negus 1927). The biological advantage to the rodents then is that the animal may continue to eat or swallow without pausing to sniff for potential predators (Gautam and Verhagen 2012).

Chemical signals have advantages over other types of signals because they remain in the air or on the surface for prolonged periods of time, even after the signaler has left. This allows a rodent to depart from a potentially dangerous situation and enables them to communicate with others (Bradbury and Vehrencamp 2011). Rodents use chemical signals to mark territories and for sexual selection. These signals remain in the environment for prolonged periods of time which allows animals to be cryptic when signaling to avoid predation. The olfactory sensory system is characterized by the detection of a chemosignal (odor or scent), or any combination of chemicals emitted, that is detected by the olfactory receptors (i.e., odorant receptors) located at the olfactory

epithelium. The information obtained from the environment is received by the olfactory receptors and transmitted through the sensory neurons to the olfactory cortex. The olfactory system is highly related to taste perception due to the role of retronasal olfaction in taste. Substances released from food and drinks inside of the mouth form the retronasal odor as they travel to the olfactory epithelium.

Olfaction has been studied *in vivo* by using odorants to stimulate olfactory receptor neurons. Behaviorally, discrimination studies have been conducted to evaluate whether rats can tell different odorants apart (Gautam and Verhagen 2012). Aside from laboratory discrimination studies, wild rodents can be examined for their behavioral or physiological response to different types of odorants such as urine from a conspecific.

Studies on golden hamsters and meadow voles (*Microtus pennsylvanicus*) have reported on the responses of individuals to olfactory cues from conspecifics and heterospecifics (Ferkin et al. 2010). These chemosignals help rodents respond to the social context, age, and conditions of senders and receivers. Just like in other modes of communication, olfactory signals are most effective if they are able to be sent by a signaler and then detected and interpreted by a receiver. The behavioral responses of rodents to chemosignals have revealed that scent-marking signals convey information to the receiver about the sender's state, phenotype, and genotype. These signals are often individually distinct. The subsequent response of the receiver is dependent on their cognitive abilities as well as a desire to increase their survival and fitness.

One example of a rodent that uses olfactory cues to avoid predation is the California ground squirrel (*Otospermophilus beecheyi*). These squirrels have a specific, innate, defensive odor response to avoid the scent of their natural predator, the Pacific rattlesnake (*Crotalus oreganus*). This odor is specific to the predator species and does not generalize to all snakes (such as the Pacific gopher snake, *Pituophis catenifer catenifer*, another snake that they may encounter but is not their natural predator). Rats also use a combination of olfactory cues and social learning

to learn about the location and identity of food sources and to distinguish between potentially dangerous and bountiful new sources of food. Rats will sniff a conspecific and modify their food choice behavior in response to the olfactory cues present on another rat.

Olfactory cues can also be important for individual recognition. In mice, major histocompatibility complex (MHC) proteins contain hundreds of alleles which reflect chemical individual identity. These MHCs are in sweat, urine, and other secretions which enable individuals to use their olfactory system to avoid inbreeding with close relatives, abort pregnancies when threatened by strange males, identify kin with which to cooperate, or learn to identify specific individuals in groups (Bradbury and Vehrencamp 2011). As such, in house mice (*Mus domesticus*), intruders are met with aggression if they do not have the proper olfactory marks.

Lifestyle choices play a role in how rodents respond to different chemosignals. For example, prairie voles (*Microtus ochrogaster*), a socially monogamous species, can detect and discriminate between different individuals' chemosignals and show partner preferences for familiar opposite-sex conspecifics over novel opposite-sex conspecifics (Blocker and Ophir 2016). In contrast, montane voles (*Microtus montanus*) and meadow voles (*Microtus pennsylvanicus*), two polygamous species, showed partner preferences for novel opposite-sex conspecifics over familiar opposite-sex conspecifics (Gobrogge and Wang 2016).

The olfactory system's far-reaching implications in mating, individual recognition, communication of defense signals, and foraging push it to the top of the list as one of the most important sensory systems across the order Rodentia.

## Tactile

Touch is a universal sensory system that is important for social grooming, communication, and bonding. Tactile information in humans has the largest sensory receptor sites in the hands; however, in rodents, information received anywhere on the body can convey crucial information as to the location of a potential threat, or social cues,

such as play or aggression. In rats, the somatosensory cortical areas devoted to the representation of the nose, whiskers, mouth, forepaw skin, and whisker-like hairs under the rat's wrists have the greatest sensory representation of all other body parts with more sharply defined receptive fields (Hermer-Vazquez et al. 2004).

Whiskers are one type of a specialized touch organ that, when deflected, give information about the direction, velocity, and duration of vibrational movement, giving an animal information about the location, size, texture, and other tactile features of objects. In mice, the quantity of the cortex dedicated to the whiskers is greater than that of the paws, with each whisker sending about 100 myelinated fibers via the trigeminal nerve to the somatosensory cortex. The mapping of the mouse whisker barrels in layer IV of the cortex has 1500–2500 neurons, and each barrel corresponds precisely to the number and arrangement of whiskers on the face.

One way touch is measured in rodents in the laboratory is through physiological studies that measure cortical responses to tactile stimulation. For example, in rats evoked response latencies in the cortex can be measured in response to whisker stimulation (Shuler et al. 2001). Cells responsible for touch sensation in the forelimbs of squirrels have been mapped in the cortex using histological analyses (Thorington Jr. et al. 1997). Observational studies in several species of rodents have studied the behavioral responses of animals to tactile stimulation from a conspecific. For example, individual rats attempting to engage in play will provide a categorically different sequence of tactile stimulation to a receiver in order to signal their intentions (e.g., huddling and rump biting).

Rats and mice also have specialized tactile neural mechanisms for tickles and itches. In laboratory mice whose itch neurons in their spinal cord were eliminated, the injection of a chemical that makes them scratch led to no itching behavior. In rats, cells in the trunk area of the somatosensory cortex of their brains fire at higher rates when they are being tickled. Tickling also leads to higher instances of play behavior in rats, suggesting that tactile stimulation similar to this by

conspecifics may be important for communicating intentions to play in rats.

Mating signals are also usually visual, olfactory, and tactile in rodents. Olfactory signals can be slow, and auditory signals can be too conspicuous; therefore, tactile stimulation can provide the quickest and most effective means of communication of intention to mate. For example, in mice and rats, prior to mating, the animals will engage in active genital sniffing, climb on top of a potential mate, and brush up against them.

The tactile sensory system in rodents has widespread implications for navigating social situations and environments. Effectively interpreting these signals can be the difference between engaging in social play or a potentially aggressive social situation and shutting away from a predator that is nearby.

## Vision

The visual system is one of the most largely studied sensory systems, from simple perception of things like spots and stripes, or discrimination of lines of different orientations, to color perception. The major sensory organs involved in the visual system include the eye, the optic nerve, and the primary olfactory cortex. Within the eye are highly complex layers of cells that reflect, refract, and detect light from the environment which is then translated into neural signals to be interpreted in the brain. The small body size of many rodent species limits the visual resolution at long distances, and their color vision is often less precise than black and white detection. This, coupled with the need for a direct line of signal transmission, makes visual stimulation a closer range sensory system for rodents.

In the laboratory, several aspects of vision have been studied in rodent models. For example, depth perception has been evaluated in golden hamsters using visual cliff paradigm, similar to what is used in human infants, where subjects are faced with what appears to be the edge of a cliff with a patterned floor and if they can perceive depth differences, they will not go past the edge (Keselica and Rosinski 1976). Object identification can be tested in a visual open field test where food items are scattered around a grid and subjects

are tasked with locating the food objects. Lesion studies have been conducted to evaluate the role of different visual associated areas in the brain in specifying the location and distance of an object.

The acuity of the visual system in rodents varies widely. For example, visual acuity in the naked mole rat (*Heterocephalus glaber*) is considered poor because of their degenerated eye and optic nerve (Crish et al. 2006). Naked mole rats typically reside in subterranean burrows that have poor visual cues due to being underground, making vision a less crucial sensory system for navigating their environment and survival. However, anatomical studies in naked mole rats have revealed that there are intact neural connections to major visual subcortical regions in the brain similar to seeing rodents. This suggests that, while blind to tasks like identifying whole objects, naked mole rats may still be able to detect differences between light and darkness (Crish et al. 2006).

Rats are nocturnal, which means that they are more active at night. Cones, the sensory cells in the eye responsible for color vision, are less active in the dark. Rods, responsible for black and white detection, are more active in the dark. The retina in rats is rod-dominated, but rats also have two types of cones corresponding to different wavelengths along the electromagnetic spectrum (Walls 1934; Jacobs et al. 2001). The characterization of rats as dichromats means that they can see only two wavelengths (blue and green), but not red. Some research suggests that a small proportion of cones is also sensitive to ultraviolet light (Jacobs et al. 2001). Rats also use environmental geometry and patterns as a cue to the location of food sources. Lab rats searching for food that is located on top of a vertical pole are able to use a painted pattern on the pole as a cue, but can also use the geographic spatial location as a cue to reliably determine the source of food (Vorhees and Williams 2014).

The visual system plays a crucial role in food acquisition, mating, and navigation in rodents. This system needs to be intact, especially in terrestrial environments, to effectively evaluate whether a situation is safe or dangerous.

## Conclusion

Rodents are highly social creatures that rely on complex integrated sensory systems for survival. They are often prey species, which makes it essential for them to utilize information that is obtained from several of their senses to safely engage with their environment, conspecifics, and heterospecifics. The biological advantages of highly specialized sensory systems enable rodents to utilize the auditory, gustatory, tactile, olfactory, visual, and vestibular information to engage with their environment, other conspecifics and heterospecifics, and to avoid predation. These systems are highly variable in sensitivity across species but are highly adaptive to the primary living and social environment of the species.

## Roger K. Thomas

Roger K. Thomas  
Department of Psychology, University of  
Georgia, Athens, GA, USA

Roger K. Thomas, Age 69 in 2008

## Birth to High School Graduation

Thomas was born on September 14, 1939, in Americus, Georgia, Sumter County. Sumter County is also the lifelong home of USA

President Jimmy Carter. Due to the relative brevity of this bio sketch, family history will be omitted except to note (a) should they live until October 14, 2020, he and Anne Easley Thomas will have been married 60 years and (b) that his ancestors include several Patriot soldiers who served in the American Revolutionary War.

Thomas changed schools nine times from grades 1 through 8. However, he attended all high school years at Glynn Academy, a public high school founded in 1788 in Georgia's Glynn County. Glynn Academy is notable (a) for its original charter that provided for the education of girls and boys and (b) for being the second oldest, continuously operating public high school in Georgia and the fifth oldest in the USA.

Thomas enrolled at Georgia Southwestern College (GSC) a 2-year college in Americus, GA in 1957. He earned an Associate of Arts degree in 1959 with the highest-grade average among male students. During the two years at GSC, he worked from September 1957 until June 1958 for a funeral home that also provided ambulance services. Among his experiences were seating attendees at memorial services, driving a hearse, driving a family car, witnessing the closing of graves as required by law, and occasionally assisting the mortician. His most exciting ambulance run was a full emergency run from Americus, GA to Emory University Hospital in Atlanta, GA, a distance of 125 miles. Thomas' role was limited to helping to load and unload the patient; a cardiologist and a nurse attended the patient during the run.

From June 1958–May 1959, Thomas was radio announcer for a station that operated from official sunrise to sunset. He worked from mid-morning Saturday to sunset and all-day Sunday. After noon on Saturdays, he was alone unless an engineer was needed. Thomas read the news, weather, etc. from Associated Press, read commercials or played tape-recorded commercials, and played records. On Sundays, one of the local African-American funeral homes sponsored live music from a studio, which Thomas could observe from his broadcasting booth. The music was mostly a *capella* singing with infrequent piano or guitar accompaniment. These were amateur

musicians chosen by the funeral home, rarely the same from one week to the next. Thomas expressed regret that he lacked the foresight to record and preserve that truly authentic, African-American gospel music.

In the summer of 1959, Thomas enrolled at the University of Georgia (UGA). UGA is the oldest chartered state university in the USA (1785); however, the University of North Carolina enrolled students first. UGA was on the quarter system when Thomas arrived, and Thomas completed all requirements for the B. S. degree in Psychology Winter Quarter, 1961, which coincidentally was the quarter when UGA's first two African-American students, Hamilton Holmes and Charlayne Hunter, were enrolled under a federal court order. They had transferred as Juniors and both graduated in May 1963.

Holmes was Emory University's first African-American medical student. He became an orthopedic surgeon in Atlanta and Associate Dean of the Emory University Medical School. Hunter's degree was in Journalism. Her employment began with *The New Yorker* and later as CNN's correspondent in South Africa. Calvin Trillin (1964) chronicled some turbulent events associated with UGA's integration. Later, Hunter-Gault (1992) described her experiences. First Hunter-Gault and later Hamilton Holmes reconciled with UGA. In 2001, UGA renamed an historic campus building, the Holmes-Hunter-Gault Building.

## Graduate Education

Thomas's enrollment in Graduate School was unplanned and fortuitous. One of his teachers in his next-to-last undergraduate quarter, Robert Travis Osborne, did not post grades. Osborne told the class that if one wanted her/his grade, she/he would have to come to his office or wait to receive it in the mail. Osborne was Director of UGA's Guidance and Counseling Center where his office was located. Almost by chance, and while his wife waited in their car to go home for Christmas, Thomas went to get his grade. When Thomas returned to the car, Osborne had assured him he would be accepted

to Graduate School and he would immediately have part-time employment equivalent to a graduate assistantship in the Guidance Center.

Osborne supervised Thomas's M.S. thesis, *Intelligence and Socioeconomic Status: A Longitudinal Study with the Wechsler Intelligence Scale for Children* (WISC). Osborne had a grant from the Educational Testing Service to conduct a longitudinal study of IQ test scores, and Thomas was one of the field test examiners pre- and post-first grade.

Informally, Thomas saw evidence suggesting that attending first grade reduced IQ test score differences among socioeconomic classes. David Wechsler visited Osborne, and Osborne asked Thomas to describe his research to Wechsler. Wechsler told Thomas he would not find anything, because their standardization procedures were too good. Wechsler was wrong; Thomas did find reduced differences among socioeconomic classes on some subtests of the WISC. Thomas's M. S. degree was conferred in 1963.

Thomas's interest turned to the study of brain and behavior, and his new Major Professor was Lelon J. Peacock. Osborne was gracious about Thomas's change, and they remained friends until Osborne died in 2013, 5 months short of age 100. Thomas was Executor for Osborne's Estate, which was gifted entirely to UGA (\$5,375,000.00).

Word limits prevent describing Peacock adequately as a mentor, but he challenged his students unrelentingly and compelled them to be self-sufficient. Peacock hired Thomas as research assistant on his NSF grant. Peacock and a UGA electronics shop partner invented a complex electronic apparatus to measure the activity of rats (see Peacock and Williams 1962). On Thomas's first day as research assistant, Peacock handed him an electronics diagram scrawled on butcher paper and told Thomas to "build it." Thomas knew nothing about electronics. Peacock told him to buy the *Radio Amateur's Handbook* and learn chapter 1. That was the only help Peacock gave. Daily when Peacock checked on Thomas laboring away, he would mutter "it won't work." It worked well enough, although Peacock had to give it a few tweaks. Thomas's

Ph.D. dissertation was *Immediate and Subsequent Effects of Brain Damage in Rats*, and the Ph.D. degree was conferred in 1965.

### Postdoctoral Fellowship

In September 1965, Thomas began a postdoctoral fellowship in the interdisciplinary Center for Neurobiological Sciences in the University of Florida's Medical School. Thomas's home department was Neurosurgery. His primary mentor was Frederick A. King, a physiological psychologist, and his secondary mentor was Lamar Roberts, Chief of Neurosurgery. Thomas's main research compared squirrel monkeys with frontal lobe lesions to control monkeys. Performances were similar for all of the lesioned monkeys but differed from the control monkeys in nearly identical classical and instrumental conditioning tasks. A tone signaled the possibility of a mild foot-shock. In the classical task, the experimenter determined when shock was delivered. In instrumental conditioning, leg flexion as soon as the tone was presented enabled the monkey to avoid foot-shock. With both tasks, the lesioned monkeys responded significantly faster than the control monkeys, suggesting that frontal lobe lesions resulted in release of inhibition.

In 1966, Thomas was chosen one of 10 "outstanding young psychologists" by the American Psychological Association. The award was a trip to Moscow to attend the International Congress of Psychology. Seven of the 10 were Ivy Leaguers; one was from Stanford, and one was from Canada. Thomas guessed that it likely helped his receiving the award that he had passed a proficiency examination in Russian translation as one of his Ph.D. degree requirements.

### Career at the University of Georgia (UGA)

The award might have helped gain Thomas an invitation to apply for a tenure-track position at UGA in 1967. He was hired in September 1967, retired in 2002 as Professor Emeritus, and

remained at UGA until he vacated his office in July 2018.

### Teaching

Including 19 years as administrator, Thomas rarely taught more than one class per quarter or semester. He enjoyed teaching and received teaching awards, especially for his graduate classes, "Neuroanatomy for Behavioral Scientists" and "History of Psychology." More information about the range of classes taught as well as the names of mentored graduate students (27 M.S. and 21 Ph.D. degree students) may be seen on Thomas's UGA website: <http://psyc.franklin.uga.edu/directory/people/roger-k-thomas>.

### Research

Thomas's UGA website also shows that currently (January 2019), he has 120 publications and 120 regional, national, and international presentations; many are downloadable as PDFs. His research began mainly in brain and behavior, transitioned to animal cognition, and finished mostly with research in history of psychology. What Thomas believes to be his two most important articles (Thomas 1980, 1996) were theoretical-methodological.

In the context of assessing the evolution of intelligence, Thomas (1980) proposed that fundamental to intelligence was learning ability. He presented an eight-level hierarchy of learning abilities ranging from sensitization to high-level relational concepts. In Tables III and IV, he showed how relational concepts can be expanded logically to challenge even the most intelligent humans. Thomas also proposed that any and all learning tasks used with human or nonhuman animals in the past or future could be reduced to levels or combinations of levels in his eight-level hierarchy. Finally, he proposed that tasks be adapted to each species so that failure can be less likely attributed to contextual variables such as sensory, motor, and motivational variable differences as well as environmental variables (such as light, temperature, humidity, etc.) that might differentially affect the *performances* of different species and misrepresent their learning abilities.

Thomas (1996), "Investigating cognitive abilities in animals: Unrealized potential" was in a

special issue of *Cognitive Brain Research*. The cover was adapted from an illustration in his article, his article was first in the issue, and the editors singled it out in the introductory editorial as follows.

Roger Thomas describes how the various animal models of cognition function relate to each other, thereby providing a framework in which most of the following papers can be discussed. (T. Steckler & C. D. D'Mello, p. ix)

Thomas believes his best laboratory research involved tasks involving concepts such as oddity in conditional discrimination contexts. Thomas and Kerr (1976) tested squirrel monkeys using trial-unique oddity discriminanda (also known in this case as the *simultaneous discriminanda*). When oddity problems were presented on a white tray (one of two *successive discriminanda*), white signaled that the odd discriminandum was the correct choice, but on a black tray (the other successive discriminandum), black signaled that either of the nonodd discriminanda were correct choices. Burdyn and Thomas (1984) went further and successfully tested squirrel monkeys using concepts as both the simultaneous discriminanda (trial-unique exemplars of "sameness" and "difference") and the successive discriminanda (exemplars of "triangularity" and "heptagonality"). Reasoning erroneously, Thomas and Kerr (1976) concluded that the monkeys were using biconditional reasoning (e.g., *if white, then odd* and *if black, then nonodd*). Burdyn and Thomas (1984) corrected that error. In this *Encyclopedia* (see "Relational concepts and symbolic logic") Thomas examined the issues associated with determining conditional reasoning in animals.

Thomas and colleagues have also contributed importantly to the literature on animals' use of numerosness. See Thomas's entry "Relative numerosness" in this *Encyclopedia* for references and discussion.

Since 1993, Thomas began making noteworthy contributions to research in the history of psychology. For example, Thomas (2007) examined five recurring and important errors among recent history of psychology textbooks, and he discussed some of the reasons for that. Thomas

(2011) described the curious circumstances associated with the fact that the first African-American to earn a Ph.D. degree in psychology, Francis Cecil Sumner (Ph.D., 1920; G. Stanley Hall, Supervisor, at Clark University) was a member of the Southern Society for Philosophy and Psychology.

Thomas's website (<http://psyc.franklin.uga.edu/directory/people/roger-k-thomas>) shows his research-related honors, including being a Fellow in the AAAS and having served as President of the Southern Society for Philosophy and Psychology (SSPP) in 2000.

### Administration

Thomas rose through the ranks, and in Fall, 1983, his department head told the Dean he was "burned out" and wanted to be replaced as soon as convenient. Thomas felt he could endure 6 months (January to July 1), so he accepted the Acting Headship beginning January 1984. His first task was to prepare faculty evaluations for 40+ tenured or tenure-track faculty members, and it was required that the evaluations justify recommendations for salary increases.

With zero-based budgeting, that meant that, if someone got an above average raise, someone else had to get a below average raise. Thomas set out to use as much data as he could, and he created a system to turn those data into ratings on a 10-point scale in the categories of teaching, research, and professional services.

Previous Heads had used data but had not developed a standard system for processing it. Thomas discovered that psychologists, who believe in measurement in their teaching and research, do not like to be measured. One senior faculty member wrote Thomas a note saying his approach reminded him of the 5th grade. Presumably, he was referring to receiving a report card. Thomas also learned that no one was happy. Those receiving the larger raises never thought them to be large enough and those receiving lower raises were naturally unhappy.

When Spring came and it was time to appoint a regular Head, Thomas decided he could make a difference and became a candidate. At UGA, the Dean appoints the Heads for 3-year terms. The

Dean consults the faculty which votes, but the Dean is not bound by the vote. Thomas always received favorable votes.

After two, 3-year terms, Thomas sincerely informed his Dean that he too was “burned out” and did not want a third term. The Dean asked Thomas what could he do to change his mind. With little thought Thomas replied, “a \$12,000.00 raise. The Dean said, “What else?” Thomas knew he could not decline such a raise as it would thereafter be a permanent part of his salary.

Upon leaving the Headship, in 1993, after 9.5 years, he was appointed 1/3 time to be Director of the College of Arts and Sciences’ Public Service and Outreach Program. He served as Director until retirement in 2002. After retirement, he continued to teach History of Psychology once/year at the graduate level until 2010, and as this is written (January 2019) he continues to publish.

### Avocational Interests

Due to working from age 12, Thomas had no opportunity for organized sports. However, in 1970, he had the highest batting average on a softball team that won the Athens City Championship (among 68 teams). He has been a whitewater canoeist since 1974 and has canoe-camped in the Okefenokee Swamp about 10 times. Finally, he owns Gibson J-45 and a Martin D-28 acoustic guitars with which, to quote a female picker – singer friend, “we make a joyful noise.”

### Definition

The role-reversal experiment is a social cognition paradigm in which two animals first work together on a cooperation task requiring complementary roles and then switch roles to test the degree to which they take the perspective of their partner.

## Introduction

Cooperation, a widespread phenomenon across animal species, ranges from simple actions that incidentally benefit another to complex behavior coordinated in time and space. One of the most complex forms of cooperation involves complementary roles, in which animals perform different actions that contribute to achieving a joint goal. Such complementary roles have been observed in the wild, particularly in the context of group hunting, in such distantly related species as chimpanzees, lions, and hawks (Dugatkin 1997), and have recently been shown even *between* species of fish (Vail et al. 2013). However, it is unclear whether individuals performing one role learn about the complementary role of their partner by working with and observing their partner or whether they must perform the role themselves in order to understand their partner's contribution. Role-reversal experiments try to address this question using novel collaborative tasks to ensure that subjects are initially naïve to both roles.

## Procedure

The basic role-reversal experiment tests pairs of subjects, which may include a subject and a conspecific or a subject and a human experimenter, and consists of two phases. Subjects first learn to perform one of the roles in the cooperative task (*training*). For example, in the classic “communication apparatus,” partners sit on opposite sides of a platform with pairs of food cups (Mason and Hollis 1962; Povinelli et al. 1992a, b). One partner (the informant) can see the rewards but cannot access them; the other partner (the operator) cannot see the rewards but can pull a handle to make one pair of cups accessible, one to the operator and one to the informant. Thus, to be successful, the informant has to indicate the food location (by pointing or positioning themselves in front of the food), and the operator has to pull the corresponding handle. In another task by Fletcher and colleagues (2012), one partner has to push a ball down a ramp and the other has to direct it

down to the next level in order to release rewards to both partners.

After pairs are proficient at the task, they switch roles so that they now have to perform the action that their partner did during training (*role reversal*). Some studies include a third phase, in which roles are returned to the original setup. The ability to reverse roles is then measured as successful transfer (i.e., no drop in performance) when first switching roles or increased performance (e.g., higher percentage correct, decreased latency, fewer trials to criterion) either compared to the first subject in that role or to their own baseline training performance. Using the communication apparatus, rhesus monkeys showed a significant drop in performance from the last training session to the first role-reversal session (Povinelli et al. 1992b) and did not perform better in their original role after having experienced the other role (Mason and Hollis 1962). Chimpanzees have been found to transfer immediately from training to role reversal using the same apparatus (Povinelli et al. 1992a) but did not, in a different task, outperform a partner who had completed the role previously, despite their experience with the complimentary role (Fletcher et al. 2012).

## What Do Role-Reversal Experiments Measure?

Povinelli and colleagues (1992a, b) interpreted successful performance in role-reversal experiments, i.e., the ability to profit from experiences in one role when later switching to the role their partner had performed previously, as evidence of role- or perspective-taking. They argued that successful subjects must have used social attribution to infer the mental states of their partner, which facilitated their own performance when roles were reversed; thus, successful performance is taken as evidence of a theory of mind or “a simple form of cognitive empathy” (Povinelli et al. 1992a).

However, others have pointed out that subjects can learn about the second role while performing the first without having to know the partner's

mental states. For example, Fletcher and colleagues (2012) suggest that successful performance instead provides evidence that subjects form a single mental representation of the collaborative task by integrating their understanding of the complementary roles. It is this “bird’s eye view,” they argue, that then facilitates performance when the roles are reversed.

Of course, the extent to which subjects are able to understand their partner’s role while completing their own is limited by their ability to learn through observation. For example, if subjects learn about and copy not the partner’s precise *actions* (imitation, e.g., pulling the proper handle) but rather the *outcome* of the partner’s actions (emulation, e.g., food cups delivered to both partners), then observing the partner during training may not aid performance during role reversal. Indeed, the outcomes in these tasks were straightforward and had been demonstrated, so subjects could be successful without learning the partner’s specific actions. If so, differences in ability in the experiment across species may simply reflect differences in social learning strategies (see Tennie et al. 2009). In fact, emulation or imitation may not be required at all; successful performance in this task may simply be due to local enhancement effects, in which the partner’s action directs the subject’s attention to the relevant part of the apparatus. In such a case, it might not even be necessary that the subjects understand the necessity of their partner, which would indicate that these tasks are not measuring role reversal so much as how they understand the apparatus. Indeed, understanding their partner’s complementary role was not necessary for subjects to successfully complete the tasks used to date.

Finally, failure to reverse roles in this paradigm may be the result of experimental factors, many of which are common problems in comparative cognition research. One issue with the studies to date is that subjects have had vastly different rearing and testing histories (e.g., juvenile rhesus monkeys that had been separated from their mothers at birth, to chimpanzees with extensive human contact and experience with numerous cognitive experiments), which limits the extent to which we can make cross-species comparisons. This is

further complicated by the small sample sizes (a common problem in animal studies) and because researchers have used different criteria for successful role reversal (see above), which may measure different aspects of cognition. Further, one might assume that in a cooperation task such as this, the subjects’ relationship with the partners would influence their behavior. Indeed, partners during training include everything from reliable human experimenters to trained conspecifics to conspecifics who learn their role at the same time (and are therefore presumably much less reliably good at the task), making it difficult to disentangle the role of the subjects’ knowledge and skill.

There are also methodological differences. Aside from differences in procedure, even when an identical apparatus is used, the different dimensions and test setups can make it more difficult for subjects of some species pairs to see (and therefore presumably understand) what their partner is doing. Similarly, some required actions, such as pointing, may be frequently observed in one species (such as chimpanzees) but may need to be shaped through extensive training in another (such as rhesus, Povinelli et al. 1992a, b). Actions that require extensive training may not be fully understood by the partner based solely on observation, either, because rather than just apply a known behavior, the subjects must first learn the behavior and then apply it correctly.

## Conclusion

The role-reversal paradigm offers an interesting experimental approach to studying complex forms of collaboration in which animals complete different, complementary roles to achieve a joint goal. However, there is currently little consistency in the criteria used to measure successful role reversal or agreement on what success at the task (or lack thereof) actually means. Whether subjects understand that they need a partner in the first place (e.g., will they wait for or recruit a partner?), and how their relationship with the partner (e.g., is the partner a conspecific or a human? Are only socially tolerant pairs successful?) and their rearing and

testing histories affect their performance in this task have not been addressed in depth. Further, it is not even clear whether animals' behavior would change if an understanding of the partner's complementary role was necessary to complete the task successfully, because it is not known whether they can solve the task without this knowledge. Although studies using this paradigm have thus far focused on primates, wide arrays of other species are known to collaborate by performing complementary roles. Thus, a comparative approach will be key in order to better understand whether and how perspective taking is required for the evolution of complex coordination.

## Roles of Medial Prefrontal Cortex Activity in Human and Animal Social Learning

Nadia Nieves and Claudius von Schroder  
The New School for Social Research, New York, NY, USA

## Established Functions of the Medial Prefrontal Cortex in Human and Nonhuman Animal Cognition

Research over the last two decades has seen advancements in neuroimaging techniques that reveal functional specialization within the prefrontal cortex (PFC) of the brain. Evidence thus far has implicated the PFC as the brain region responsible for high-level behavioral regulation via inhibition, executive function, and facilitation of complex social behaviors. Activation in subregions of the PFC, such as the medial prefrontal cortex (mPFC), is found to correspond with measurements of higher-order cognitive processes critical for learning, including attentional processes, decision making, and working memory (Hoover and Vertes 2007). The mPFC has been studied predominantly in rodents and rhesus monkeys. Derived analogue models of the brain suggest that mPFC is both anatomically and functionally similar to the human dorsolateral PFC (Goodell et al. 2017).

While literature has thus far focused on the mPFC as a site associated with perceptual functioning, including attention and memory (Siddiqui et al. 2008), few discussions have explicated its role across social-cognitive development. Recently, emerging interests have led to the discovery of the mPFC's importance in social processing and learning. Both animal and human studies indicate that the mPFC is involved in moral reasoning, mentalizing, monitoring, and predicting others' behaviors as well as person perception. This review attempts to elucidate the role of the mPFC in guiding social learning and

predicting positive and negative outcomes of others' actions (e.g., Apps and Sallett 2017) through examination and discussion of extant neuroimaging and neuropsychological findings across animal and human research. Directions for future research will also be presented, such as those that investigate the mPFC and related circuitry underlying emotional and social processing in both human and animals.

### **Initial Evidence for mPFC Role in Memory and Higher Cognitive Processes**

Interest in the mPFC region was previously limited to its relationship with the anterior cingulate cortex (ACC) in facilitating purely cognitive processes such as memory and attention, having little to no involvement with emotion processing or social behavior in both humans and animals. For example, studies have shown involvement of the mPFC in short-term and long-term memory and more complex cognitive processing to aid in guiding behavior and decision making. Due to differences in methodology, research has produced inconsistent findings on the mPFC's contribution to cognition (Alexander and Brown 2011). These discrepancies in results impose challenges for theoretical models to explain the purpose of the ACC/mPFC relationship in higher-order functions. Some results show significant involvement of the mPFC in the motivational aspects of attention, error detection, learning from aversive outcomes, and executive functions (Apps and Sallett 2017).

Past studies have highlighted the role of mPFC in memory function through consistent results showing decreased performance on recall tasks when the mPFC was inhibited during learning (Euston et al. 2012). Results have suggested that the mPFC tracks "remote" memories consisting of information learned more than one week before the date of attempted retrieval (Takashima et al. 2006). Additionally, mPFC inactivation has been associated with impaired retention of fear-related memories when tested one day after exposure to fear stimuli, suggesting its role in "recent memory" formation. Still more studies show that

mPFC interference immediately following a learning period inhibits later recall ability, pointing to the role of the mPFC in memory consolidation, i.e., long-term memory. In short-term memory, mPFC lesions lead to recall deficits for location-specific reward associations over delays of 30 min (Seamans et al. 1995). These results demonstrate the importance of mPFC activation in long- and short-term memory and recent and remote memory. However, more functional specializations in the mPFC have been found in recent studies, adding to the variety of functions carried out by this area.

Despite its overlap with memory functions, what differentiates the mPFC from other brain areas is its critical role in directing adaptive behavior (Euston et al. 2012). Evidence suggests that the mPFC uses the aforementioned memory systems to store and process contextual information to produce an adaptive response. Specifically, combined electrophysiological and anatomical findings in rat studies indicate that the mPFC takes current contextual information to predict the most adaptive response in particular situations, based on remembered experiences (Euston et al. 2012). This forms a kind of behavioral feedback loop where the organism learns new adaptive behavioral responses based on the alignment of previous responses with environmental expectations and conditions (i.e., context).

Electrophysiological studies show divergent specializations pertaining to specific subregions of the mPFC, where the internal structure of this system can be divided on a dorsal-ventral gradient: Activity in the dorsal mPFC (including the infralimbic and ventral prelimbic cortex) appears to be strongly associated with musculoskeletal action, whereas activity in the ventral mPFC (including the dorsal prelimbic and anterior cingulate cortex) is more associated with reward-dependent outcomes, i.e., emotional control (Euston et al. 2012). Dorsal mPFC regions thus receive input from motor areas of the brain to produce adaptive action, and the ventral mPFC receives input from emotion-related brain regions, producing adaptive emotional responses based on reward contingencies. As such, the input/output differences occurring between the subdivisions of

the dorsal/ventral mPFC gradient account for the processing of motivational stimuli on the one hand and control motor activity on the other.

To learn adaptive behavioral skills, the mPFC's feedback mechanism initially tracks contextually relevant environmental information that is motivationally salient with help from the hippocampus. The mPFC relies on the rapid associative functions of the hippocampus to learn from spatial and emotional cues quickly, as it binds associations between contexts, events, and responses (Hirel et al. 2013), helping the mPFC obtain maps of its inputs and outputs based on associations of motivationally salient cues. As associations become routine, the mPFC begins to store feedback information locally – independent of the hippocampus – in the form of schemata (Euston et al. 2012). This transition is largely due to memory consolidation, where memory is consolidated in the mPFC during periods of reactivation, mirroring hippocampal “sharp waves” with high-density field potential oscillations (Euston et al. 2012; Johnson et al. 2010). Again, this is suggestive of the role long-term memory plays in mPFC functioning.

The learning of adaptive behavior as a result of mPFC functionality also extends to emotion regulation. For instance, the relationship between the mPFC and ACC is implicated in negative and positive emotion appraisal and expression (Etkin et al. 2011). mPFC connectivity with regions of the limbic system such as the amygdala, periaqueductal gray, and hypothalamus supports complex processing of emotional information via top-down processing. These connections form a network that supports working memory (Etkin et al. 2011) and serve as a basis for integrating emotional information into memory processing. Further studies demonstrate that greater activation in the ACC and mPFC is associated with the regulation and sensitivity of negative emotions (i.e., disgust), as well as the expression of negative emotions such as pain and empathic concern (Ochsner and Gross 2008). Extinction of fear and appetitive learning, as well as processing anger, activates the ventral and dorsal regions of the mPFC, respectively. These findings provide further support for the idea that intact mPFC

connectivity to subcortical regions is fundamental to processing and responding to emotional stimuli in social contexts.

Prior studies on mPFC functionality provide evidence for a division of labor in emotion processing, where mPFC subregions work independently to regulate fear. Similar to the aforementioned anatomical division between motor- and reward-based input/output configurations, these emotion-oriented subregions include dorsal areas (prelimbic/dACC) which regulate fear expression and ventral areas (infralimbic/vmPFC) which regulate fear suppression (Giustino and Maren 2015). The body of research presented here demonstrates the importance of an intact mPFC in learning, memory, and emotion regulation, the latter being crucial for adaptive social behavior. It is thus important to understand how the mPFC is involved in different types of social learning, cognition, and behavior.

## mPFC Role in Social Cognition and Learning

Here, we refer to social learning as (a) the formation of emotional responses to others' behaviors, facial expressions, and speech, (b) formation and maintenance of expectations about social environments, and (c) decision making processes related to social interactions. Recent studies have shown that the mPFC has been implicated in “processing, representing and integrating social and affective information” (Grossman 2013, p. 1). Additional studies demonstrating social learning processes in the mPFC involve self-reflection, person perception, and theory of mind/mentalizing (Amodio and Frith 2006), understanding self and others, decision making in adults (Heekeren et al. 2008), predicting others' preferences (Kang et al. 2013), and learning and predicting the likely outcomes of actions of the self and others (Alexander and Brown 2011). Additionally, it has been demonstrated that the mPFC is implicated in facilitating coordination between animals, regulating social interactions, and carrying out complex defensive behaviors (Goodell et al. 2017).

In fact, functionality of the mPFC is implicated in social learning very early on in development. According to a review of infant studies on the PFC by Grossman (2013), mPFC lesions lead to anti-social behaviors such as interpersonal violence, vandalism, and stealing. In terms of moral reasoning, mPFC lesions lead to more utilitarian, ego-centric responses to moral dilemmas, decreased willingness to resolve interpersonal conflicts, and consideration of the consequences that behavior has on others and dysregulated autonomic responses to punishment (Grossman 2013). This pattern of results suggests that damage to the mPFC has severe consequences for social functioning; in terms of development, the mPFC seems to be less plastic than other areas of the brain (Thomas and Johnson 2008).

The formation of expectations in social situations is an important aspect for successful interpersonal attachments and relationships. In a speed-dating experiment with human participants, Cooper and colleagues (2014) found that expressions of interest in potential partners, as well as feelings of rejection, were associated with increased activation in the posterior superior temporal sulcus and the rostromedial PFC. The mPFC specifically responded to prediction errors from the reinforcement-learning model of personal desirability, suggesting that predicting and expressing both desirability and rejection involve a quantitative calculation in neural networks responsible for processing social rewards (Cooper et al. 2014). This study provides further evidence for the role of the mPFC in forming social expectations that are informed by emotions.

The mPFC promotes the ability to monitor others' actions and detect errors in others' actions, an important factor in successfully responding to others in interpersonal interactions. In a study of two monkeys, Isoda (2017) found that when monitoring both the individual and the others' actions, differing neuronal populations in the mPFC coded divergently for actions pertaining to the individual versus actions pertaining to the other. When another monkey committed errors in its actions, mPFC neurons demonstrated a phasic increase in activity, suggesting that the mPFC is biased toward social information that would inform future expectations.

Neuroimaging findings in humans show that a newborn's mPFC activity significantly increases in response to a mother reading a book using infant-directed speech, as opposed to a mother reading in adult-directed speech. This suggests that the mPFC aids in motivating attention toward cues that are socially interactive (Saito et al. 2007). The mPFC might thus be involved in learning from others by detecting the relevance of others' actions with reference to the self.

Recent evidence highlights the mPFC's direct involvement in regulating aggressive behaviors. According to Goodell et al. (2017), aggression observed in rodents may be directly associated with changes in mPFC function due to post-weaning social isolation (PSI) may be directly related to aggression in rodents that were previously exposed to PSI. Intuitively this would make sense, as emotion regulation and executive functioning are both strongly related to mPFC functionality (Goodell et al. 2017). In addition, a decrease in executive functioning has previously been linked to an increase in physical aggression, supporting the notion that mPFC functionality would be involved. Other studies linking mPFC abnormalities to PSI provide evidence for atypical changes in structure and function, including a dampened expression of early genes (Wall et al. 2012), dendritic spine morphology (Ferdman et al. 2007), and synaptic-related proteins such as PSD-95, a protein involved in synaptic plasticity, (Hermes et al. 2011). In a study using optogenetic stimulation, increased stimulation of the mPFC demonstrated a decrease in aggression in mice; optogenetic silencing, on the other hand, showed a marked increase of aggressive behaviors (Takahashi et al. 2014). Demonstrating increases of FOS (a family of genes responsible for regulating cell proliferation, transformation, and differentiation) in the prelimbic area (PL), results from Goodell et al. (2017) support previous findings that socially dominant mice expressed higher levels of the c-FOS gene in the PL subregion of the mPFC (Wang et al. 2011). Their results indicate an elevation in social rank when rodents interact with other nonaggressive rats, revealing mPFC functional sensitivity to the behavioral characteristics of stimulus rats. Finally,

changes in PSD-95 punctae in the ventral mPFC of isolated rats with social learning differences indicated more time spent with aggressive stimulus rats. Their results insinuate that social isolation may play a causal role in the maintenance of abusive social behavior.

A few theoretical orientations have arisen from these results. According to the somatic marker hypothesis (Damasio 1996), information from the ventromedial PFC and orbitofrontal cortex contains somatic markers that allows learning by experience by linking experiential contingencies with previous emotional experience. For individuals with vmPFC damage or dysregulation, effectively utilizing context-appropriate somatic markers becomes difficult, resulting in behavior and cognition that appears similar to sociopathy (Siddiqui et al. 2008). mPFC dysfunction has also been implicated in other clinical disorders including schizophrenia, bipolar disorder, and autism spectrum disorder in which social impairment is a main characteristic (Goodell et al. 2017).

Both human and monkey fMRI studies demonstrate that learning to anticipate the value of actions and forming expectations about actions, as well as detecting unexpected outcomes, seem to be important processes aided by the mPFC. Alexander and Brown's (2011) theory and model of mPFC function referred to as the predicted response-outcome (PRO) model suggests that: "individual neurons generate signals reflecting a learned prediction of the probability and timing of the various possible outcomes of an action. These prediction signals are inhibited when the corresponding predicted outcome actually occurs. The resulting activity is therefore maximal when an expected outcome fails to occur, which suggests that mPFC signals in part the unexpected non-occurrence of a predicted outcome" (p. 2). Instead, it maps existing action plans in a stimulus context to predictions of the responses and outcomes that are likely to result, i.e., response-outcome learning. It allows multiple possible action outcomes to be predicted simultaneously, each with a corresponding probability (Alexander and Brown 2011).

As previously stated, the majority of research relating the mPFC to social cognition is based on

studies examining the sulcus of the ACC – specifically, the sulcus of the ACC (ACCs) – and pertains to the ACCs's influence on reinforcement learning (Kolling et al. 2016). To recapitulate, reinforcement learning theory (RLT) states that the ACCs anticipate and monitor the value of behaviors by evaluating the differences between behavioral outcomes and expectations, yielding a prediction error (PE) (Apps and Sallet 2017). Impaired PE coding is strongly associated with impaired social cognition (Hill et al. 2016), as PEs inform future-oriented decision making, learning, and adaptive behavior. These recent findings mark the beginning of a social learning-focused model for mPFC function in which the avoidance and anticipation of social errors influence social behaviors. However, not much is known regarding more complex and specific social behaviors in humans.

A study conducted by Kumaran et al. (2016) provides new evidence for how social hierarchies, defined by status inference, are learned. The study suggests that the degree of change in an individual's perception of social hierarchies fluctuate depending on whether they are self-relevant or not. In their study, participants were asked to differentiate the social status of individuals based on whether they belonged to either a "self-hierarchy" – the one to which individual participants themselves belonged to – or an "other-hierarchy," which included strangers, as well as acquaintances and close friends (Cikara and Gershman 2016). How much the participants' belief about social status changed due to feedback was associated with increased activation in the mPFC, amygdala, and hippocampus. According to Kumaran et al. (2016), these brain regions thus form the basis of a "social status inference engine," in which the mPFC pertained specifically to changes in belief regarding the self-hierarchy condition, i.e., when participants demonstrated a bias toward their own social status. This is corroborated by mPFC regions (including the pregenual anterior cingulate) that are correlated with thoughts about one's own personal traits, mental status, and characteristics (Jenkins and Mitchell 2011). The role of the mPFC is further supported by its designation for representing others who are

characteristically similar to one's own traits. Kumaran et al.'s (2016) results highlight a condition where the mPFC is only able to make representations of others when the "self" is used as a diagnostic template (Cikara and Gershman 2016). In other words, the mPFC uses information that is self-referential when making judgments about others who exhibit similar traits. Self-referencing is not relevant when beliefs about a hierarchy pertain to another hierarchy; thus the mPFC only seems to code for the behavior of others when they are similar to one's own behavior (Cikara and Gershman 2016). These results support Festinger (1954), who established the idea that evaluations of self-referential behaviors are acquired via social comparisons with others that exude behavioral characteristics similar to one's own.

In sum, experimental data on human and non-human animals demonstrate the crucial role of the mPFC in social learning and cognition. We have established that the mPFC, due to its functional connectivity to subcortical regions of the brain, informs social learning processes via emotional and motor inputs, error detection and predictions, and self-relevant information. The present review has demonstrated that the mPFC is important for far more complex social and emotional behaviors than purely higher-level cognitive/perceptual functions, as previously thought.

## Future Directions

The current review of the literature on the role of the mPFC in social learning suggests that more research focused on specifying the preference for varying types of social information in the mPFC is needed. In addition, there is a lack of research on mood and anxiety disorder-related effects on mPFC activation during social learning tasks. This type of research would help identify which components of social learning processes are affected by mPFC dysregulation caused by psychopathology. More research looking at the developmental pattern of mPFC activation during social cognition tasks would determine whether the role of the mPFC changes over time. In

addition, continued mPFC neuroimaging research in clinical samples could inform treatment methods for patients diagnosed with various communication disorders and psychopathology. For example, transcranial magnetic stimulation of the mPFC modulates the processing of facial expressions in a priming task. Additional research in this vein, especially with clinical samples, could further our understanding of how social information, such as faces, are processed in clinical disorders and how TMS techniques can be applied to remediate dysfunctional information processing in the brain and positively affect emotional experiences of others.

In addition, several studies have been limited by possible confounding results stemming from overlapping brain areas. In some cases, it is unclear whether a lesion-based finding is the result of one distinct brain area or due to the effects of another overlapping area. Furthermore, it has been found that surrounding brain regions are able to compensate for loss in a proximally related region. Hence, more studies involving single unit recordings and neuropsychological studies showing double dissociations that measure causal factors responsible for functional deficits due to neural abnormalities are needed.

## Ronald Schusterman

Colleen Reichmuth

Long Marine Laboratory, University of California  
Santa Cruz, Santa Cruz, CA, USA

Ronald Jay Schusterman (1932–2010) was an American comparative psychologist that contributed innovative experimental and behavioral research with humans, primates, and marine mammals from the late 1950s to the end of his life in 2010. He had a long and productive career in the biological and behavioral sciences, and his research intersected many diverse fields. He considered himself an eclectic scientist, borrowing the most useful ideas from every discipline that he encountered and blending them into a practical and synergistic approach to his studies of animal learning and behavior. Schusterman was best known for the meticulous experimental methods that he developed, refined, and applied to the research problems he explored, as well as for his dedication to searching for the most parsimonious explanations for the behaviors he observed and analyzed (Nachtigall et al. 2010).

Schusterman began his career in the 1950s working with human subjects, and also the behavior of non-human primates, including chimpanzees, gibbons, and monkeys at the original Yerkes Laboratory of Primate Biology in Orange Park, Florida (Schusterman 2010). He credited his training as a psychologist to Mortimer Fienberg at Brooklyn College, where he completed his Bachelor's degree, and Joel Greenspoon and Winthrop Kellogg at Florida State University, where he earned his Master's and Doctorate degrees. He

also credited his success to lucky timing and the support of the National Science Foundation following massive American investment in young scientists – starting in 1958 – in response to the shocking successful Soviet launch of *Sputnik I*.

Schusterman shifted his focus from primates to marine mammals during a time when little was known about these animals and their behavioral and sensory capabilities. His subsequent experimental work with dolphins, seals, sea lions, and walruses spanned nearly 50 years, a period over which understanding of these animals changed dramatically. Schusterman's early studies with sea lions were spurred by his former professor Winthrop Kellogg, who had recently reported the discovery that dolphins used specialized ultrasonic sonar to orient and to detect objects under water (e.g., Kellogg 1958). Schusterman sought to determine whether sea lions similarly used echolocation to gain information about the environment. By observing sea lions in controlled environments and training them to cooperate in a variety of behavioral procedures, he eventually found that they did not echolocate (see Schusterman et al. 2000a; Rice 2010; Schusterman 2010). Ultimately, Schusterman combined sensory and cognitive assessments to understand how sea lions and other marine mammals acquired and used information from a variety of modalities to modify their own behavior.

Schusterman's research with primates and marine mammals covered a broad range of topics that addressed fundamental topics in animal learning, including those related to the themes of *efficiency in learning*, *decision-making in uncertainty*, and *emergent behavior*. Schusterman's research in these areas relied on the basic tenants of conditioning and learning theory, which he used to develop innovative and effective methods for training animals which he studied mostly in the controlled conditions of the laboratory (see e.g., Schusterman 1980). He correlated what he learned through rigorous experimentation with observations of animals in the wild to better understand how learning and sensory capabilities might be used by individuals to solve complex social and ecological problems (e.g., Schusterman et al. 2003). Especially later in his career,

Schusterman worked to connect knowledge of species-typical behavior to understanding of proximal mechanisms that support cognition and communication (e.g., Schusterman et al. 2000b, 2002).

## Efficiency in Learning

Schusterman was intrigued by Herb Terrace's research on *errorless learning* in pigeons (Terrace 1963), which described examples of discrimination learning that occur with few or no responses to negative stimuli. Terrace was the first to show that errors are not required for successful discrimination performance to occur, but rather that gradual fading methods can dramatically reduce (or eliminate) the number of errors needed to learn new discriminations.

Schusterman immediately followed Terrace's thread by showing that similar methods could be used to accomplish complete reversals of well-established visual discriminations in sea lions, virtually without error (Schusterman 1966; Schusterman and Thomas 1966). He found that reversals of stimulus form preferences could be accomplished by progressive dimensional changes in shapes. Importantly, Schusterman measured subtle behavioral responses as well as trial outcomes, and thus, was able to determine the transition points at which the subject's attention shifted from one stimulus dimension to the other. Like Terrace, Schusterman found that learning in these optimal conditions could occur efficiently and without errors, and that subjects could learn without frustration or other emotional responses that might bias later responses to stimuli. Schusterman used variants of errorless learning procedures in a variety of different experimental contexts over the next decades (e.g., Schusterman 1980).

In the 1980s, Schusterman and colleagues discovered that sea lions were capable of *learning by exclusion*. Exclusion learning refers to behavioral control by familiar negative stimuli, or in layman's terms, decision-making by process of elimination. This type of learning has been called by many names in the

psychological literature, including "emergent mapping," "psycholinguistic inference," "disambiguation," "mutual exclusivity," and most recently "fast-mapping" (Reichmuth Kastak and Schusterman 2002a). At the time, this learning process was not well identified or described in the comparative literature, but became evident to Schusterman during his studies of complex learning and artificial language learning in sea lions (Schusterman and Krieger 1984).

During learning of conditional discriminations, or *if . . . then* associative rules, Schusterman found that sea lions could immediately relate two new items when they were paired with a familiar or incorrect alternative (Kastak and Schusterman 1992; Schusterman et al. 1993). He further saw, as did others working independently in the fields of human behavior analysis and psycholinguistics, that this type of problem solving strategy generated "learning outcomes"; that is, that after exposure to problems that could be solved by an exclusion strategy, new associations were eventually established that could be performed in the absence of familiar alternatives. In this way, new conditional discriminations could be acquired virtually without error. This was an important and effective training procedure, but also, critical to interpretations of relational learning in animals (Kastak and Schusterman 1992). The principle of exclusion improves our understanding of what individuals know about what is *not* correct, and how that knowledge can induce new stimulus relationships. The exclusion principle was evident in Schusterman's studies of artificial language learning by sea lions, enabling him to argue that linguistic competence was not a prerequisite for apparent object labeling.

Efficient learning and teaching strategies for animals were also evident in Schusterman's research with learning sets. Learning sets refer to the process of learning to learn, as described originally by Harlow (1949) – where independent but similar problems are learned faster with experience. Demonstration of learning sets relies on transfer between similar successive problems. Schusterman used visual shapes to train simple two-choice discriminations with sea lions and found a decrease in the number of errors required

to learn each successive problem, until eventually one trial or a few trial learning occurred when novel stimulus sets were introduced (Schusterman and Thomas 1966). Evidence of the learning-to-learn phenomenon in animals leading to nearly errorless learning of new relationships strongly influenced Schusterman's view that that learning benefited from exemplar training. As a result, he tended to use large stimulus sets and large numbers of training and testing problems in many of his experiments (e.g., Kastak and Schusterman 1994). In doing so, Schusterman prepared his animals for the types of test problems they would encounter later on, thus dampening responding influenced by trial novelty and enabling the use of trial-one (first exposure) measures of performance on transfer problems.

### Decision-Making in Uncertainty

Efficiency in learning and learning without errors or frustration were recurrent themes in Schusterman's work; however, errors tell us a great deal about what animals can do, and sometimes what they cannot do. This is certainly true in assessment of sensory performance, where errors reveal the limits of sensory capabilities.

Schusterman was interested in how animals made decisions in conditions of uncertainty. Throughout many of his experiments, he used behavioral observations and performance metrics to evaluate attention, motivation, and strategy during problem solving. Due to his interest in sensory biology, he was among the early psychobiologists to conduct empirical work on signal detection theory (Schusterman 1974). His rigorous work in this area revealed a great deal about learning and behavior during difficult tasks. Over the years, he and his collaborators conducted detailed and systematic experiments to explore the role of response bias in animal psychophysics (e.g., Schusterman and Johnson 1975; Schusterman et al. 1975; Schusterman 1976).

The experiments revealed that strategies and decision making during difficult discriminations are influenced by a variety of factors, including reinforcement ratios, trial ratios, conditional probabilities within trial sequences, and response

generalization. Schusterman's work helped shape our understanding of how prior experience influences decision-making in humans and other animals, and has relevance to many modern applications of signal detection theory.

### Emergent Behavior

Schusterman's most important contributions to comparative cognition come from research on what some have called emergent learning or concept learning. This refers to the emergence of new or untrained behavior from logical inferences about previously learned relationships. Schusterman considered these emergent performances examples of new knowledge arising from old knowledge, or synergistic problem solving.

Schusterman's efforts, starting in the late 1970s, to teach sea lions to comprehend an artificial gestural language led him to a rigorous experimental analysis of syntax and semantics (Schusterman and Krieger 1984, 1986; Schusterman and Gisiner 1988; Gisiner and Schusterman 1992). Following training with four *modifiers* (e.g., small, white), 14 different *objects* (e.g., ring, cone), and seven *actions* (e.g., flipper touch, tail touch), Schusterman showed that a sea lion could respond appropriately to over 7000 unique instructional sequences. Furthermore, the sea lion could answer questions about the presence or absence of particular objects in her pool, perform relational trials which required her to take one object to another, and indicate the relative size of objects. The sea lion's performance in this paradigm rivaled or exceeded that of language-trained dolphins and chimpanzees, indicating that large brains and extreme sociality were not prerequisites for highly complex associative behavior.

The results of the artificial language study clearly showed the emergence of a "slot" grammar supporting novel behavior, with apparent functional equivalences arising between signs of a given type. However, whether or not the gestural signs were truly symbols, or referential signals was difficult for Schusterman to demonstrate in this linguistic task, as the sea lions could not

“name” the objects by producing the gestures used by their trainers. Schusterman suspected that general learning processes, rather than specialized cognitive abilities like language, were involved. Instead of comprehending the instructional sequences within a linguistic framework, he believed that the sea lions, and maybe other animals trained on similar tasks, were using structured sets of problem-solving rules to succeed in the comprehension tasks.

To further explore the basis of emergent behavior in animals, he and his students began a detailed series of studies on symbolic behavior, concept formation, and memory which allowed for a deeper experimental analysis of component behavior and contextual control (for review see Schusterman et al. 2002). Strongly influenced by the behavior analyst Murray Sidman, Schusterman turned to complex discrimination learning procedures to examine the conditions which promoted emergent learning. Schusterman used highly specific training procedures with sea lions to demonstrate that these animals were capable forming an assortment of abstract concepts. These included generalized *identity* matching, symbolic matching or *symmetry*, *associative transitivity*, *stimulus equivalence*, and *functional equivalence* (Schusterman and Kastak 1993, 1998; Kastak and Schusterman 1994; Kastak et al. 2001). These concepts, once formed, proved to be highly durable, lasting as many ten years (Reichmuth Kastak and Schusterman 2002b).

The sea lions’ successful performances in these procedures, which are notoriously difficult for nonhuman animals, were attributed in part to Schusterman’s use of large stimulus sets during training. Multiple exemplars also afforded the sea lions practice with similar problems prior to testing, and enabled “trial-one” performance measures of transfer. The sea lions’ success with novel transfer problems demonstrating specific cognitive abilities provided some of the first convincing evidence that nonhuman mammals could use “rules of logic” to solve complex problems. In this sense, Schusterman was a true pioneer in the field of comparative cognition. Many of his systematic teaching methods for animals have been adopted to improve learning outcomes for language-disabled people.

## Legacy

Ronald Schusterman’s careful work in the laboratory to document the conditions under which animals gather and process information, and use it to solve a variety of synthetic and natural problems, leaves a strong empirical framework for the study of animal cognition. During his lifetime, he published more than 100 professional papers which continue to influence many studies in contemporary comparative psychology. Schusterman was a Fellow of the American Association for the Advancement of Science (1967), the American Psychological Association (1984), the Animal Behavior Society (1996), the Acoustical Society of America (1998), and a founding member of the Society for Marine Mammalogy (1981). His laboratory, which Frans de Waal has called “*the strangest and most delightful animal laboratory he ever set a slippery foot in*” (de Waal 2016, p. 181) has remained at the University of California’s Long Marine Laboratory since 1985.

## Ronald Weisman

Christopher B. Sturdy<sup>1</sup>, Marcia L. Spetch<sup>2</sup> and Laurene M. Ratcliffe<sup>3</sup>

<sup>1</sup>Department of Psychology, Neuroscience and Mental Health Institute, University of Alberta, Edmonton, AB, Canada

<sup>2</sup>Department of Psychology, University of Alberta, Edmonton, AB, Canada

<sup>3</sup>Department of Biology, Queen's University, Kingston, ON, Canada

Ronald G. Weisman made major contributions to the field of Comparative Cognition for over 50 years. Ron finished his career as Professor Emeritus in the Departments of Psychology and Biology at Queen's University located in Kingston, Ontario. Ron was born in Detroit, Michigan, in 1937 and died in Kingston, Ontario, in 2015. Ron earned a B.A. (1960), M.A. (1961), and Ph.

D. (1964) from Michigan State University. Ron's first research publications came from work that employed principles of learning in an educational setting (e.g., Krumboltz and Weisman 1962). Ultimately, Ron completed his graduate work with Jack King and M. Ray Denny studying animal behavior with a focus on learning processes in mice (e.g., Denny and Weisman 1964; King and Weisman 1964).

Following his graduate work at MSU, Ron was a National Science Foundation (NSF) postdoctoral fellow with David Premack at the University of California, Santa Barbara from 1965 to 1966. Ron was hired as Assistant Professor of Psychology at Queen's University in 1964. He was promoted to Associate Professor in 1970, again to Professor in 1977, cross appointed to the Department of Biology in 1993, and finally promoted to Professor Emeritus in 2000. In sum, Ron was a professor at Queen's for over 50 years. During his time at Queen's, Ron took up many visiting appointments at other universities, including at Duke University, Florida Tech, Johns Hopkins University, Sussex University, King's College at Cambridge University, and the University of California, San Diego.

Ron made numerous significant contributions to our understanding of animal learning, cognition, and behavior. In his early career as an independent scientist, much of his work focused on investigating the determinants of behavior, using what can be considered a traditional approach to understanding behavior: experiments conducted in conditioning chambers, using rats and pigeons as subjects (e.g., Weisman 1975). In these studies he made many contributions to understanding basic learning processes such as discrimination, inhibition, and avoidance learning. This work, although important and well regarded, is not what most people will remember as Ron's main scientific contributions. The work from the "second act" of his career is the work for which Ron will be most remembered.

In the 1980s, Ron embarked on a new career, studying all aspects of songbird vocal perception and production. Being a newcomer to the empirical study of songbirds, Ron started almost from scratch. The genesis of this new career was

Ronald G. Weisman. Ph.D., Professor Emeritus of Psychology and Biology (14 September 1937–27 January 2015)

characterized by a series of happy coincidences, a real life evolution of a research program, if you will. Around the time of his trip to San Diego, Ron had become interested in understanding how animals process information and wanted to apply *information integration theory* as a conceptual framework to do so. Up to this point, Ron had tested his ideas with pigeons as subjects but felt that studying a natural system was a better way to proceed. It was around this same time that he met Laurene Ratcliffe, who had recently started working at Queen's University, and asked her, as an expert in songbird behavioral ecology who had experience working with great tits (*Parus major*) at Oxford University, whether birdsong would be a good system to approach these questions. Ratcliffe suggested black-capped chickadees (*Poecile atricapillus*) as a potential model system because they had a two-note song that seemed relatively simple acoustically. One of the first set of studies involved conducting operant-type procedures in the field and the laboratory that showed chickadees were sensitive to the number, note type, and order of the notes in their song (Ratcliffe and Weisman 1986; Weisman and Ratcliffe 1987; Ratcliffe and Weisman 1988). Thus the simple song seemed to be not so simple upon closer experimentation. The happy coincidences continued when Stuart Hulse and Jeffery Cynx, who were already studying pitch perception in starlings (*Sturnus vulgaris*; Hulse and Cynx 1986), performed calculations on black-capped chickadee songs that Ratcliffe and Weisman reported in their 1985 Condor paper and pointed out to Ron and Laurene that chickadees produced their two-note songs with a consistent relative pitch relationship between the two notes. Once again, the "simple" song turned out to be paradoxical in its complexity embedded in seeming simplicity.

Ron forged a truly integrative research program that combined elements of learning, cognition, ethology, and neuroscience using a variety of songbird species as his study subjects (for reviews of some of this work, see Weisman and Ratcliffe 2004 and Weisman et al. 2012). Following the early success of this work with songbird perception, Ron also began to

compare the auditory perceptual abilities of songbirds with those of humans. Ron and his colleagues (notably Laurene M. Ratcliffe, T. Andrew Hurly, Daniel M. Weary, Scott A. MacDougall-Shackleton, Douglas J.K. Mewhort, Leslie S. Phillmore, Milan G. Njegovan, Marisa Hoeschele, Laurie L. Bloomfield, and Christopher B. Sturdy) uncovered aspects of songbird production and perception that were largely unknown before Ron embarked on this new research area. Among the most notable of his research findings, Ron and his colleagues described black-capped chickadee singing behavior in detail and, among other findings, showed that chickadees produce the frequency interval in their two-note *fee-bee* song with remarkable fidelity (Horn et al. 1992; Ratcliffe and Weisman 1985; Weisman et al. 1990). Moreover, Ron showed that birds could perceive this interval with a high degree of accuracy (Weisman and Ratcliffe 1989; Weary and Weisman 1991). Importantly, Ron showed that this perceptual ability and other auditory perceptual abilities and neurobiological correlates (Njegovan and Weisman 1997, Phillmore et al. 2003) were impacted if the birds were reared in conditions that resulted in abnormal vocal production. Further studies, both with chickadees and zebra finches (*Taeniopygia guttata*), revealed that songbirds far outperformed humans, even trained musicians, at frequency-based discrimination tasks (e.g., Weisman et al. 1998; for a review see Weisman et al. 2012). Later work showed that zebra finches, like chickadees, had perceptual and production deficits following manipulations of the social, acoustic environment during development (Sturdy et al. 2001). A constant theme throughout his career was the encouragement and support he provided his collaborators and trainees, imploring them and others to conduct research aimed at "explaining nature" (Weisman 2008).

Ron's career was impressive by any measure, but his impact extends beyond that accounted by metrics like number of publications, H indices, and other such measures often used for assessment. Some of the most lasting contributions

that Ron made to the scientific communities to which he was utterly devoted throughout his career defy such routine enumeration. After his death in 2015, many colleagues offered descriptions of Ron's influence using phrases such as "force of nature," "intellectually challenging," "passionate," and "inspiring." All of these things he surely was. Among Ron's many important contributions to the scientific community was his creation of an international conference designed to bring together researchers from Psychology and Biology to share their findings and insights about behavior, learning, and cognition across species. This conference, called the Conference on Comparative Cognition (CO3), started in 1994 with an attendance of approximately three dozen scientists and rapidly grew into a popular annual conference with a stable attendance at well over 100 presenters from all over the world. Over the years, there have been talks about numerous aspects of behavior and cognition on over 100 species.

In response to the growth and overwhelming success of the CO3 conference, and the recognition that a more formal organizational structure was needed, Ron founded the Comparative Cognition Society (CCS) in 1997 and was the first president of CCS. This society has grown and thrived since its founding, and Ron was awarded the CCS Research Award for his substantial contributions to the field in 2007. Ron also initiated and was the first editor and publisher of the online and open-access journal, *Comparative Cognition & Behavior Reviews*, which has published important reviews and critical commentaries on a wide range of topics in Comparative Cognition since 2006.

Rochester, MI, USA

## Synonyms

Inborn reflex; Innate reflex; Instinctive reflex; Physiological reaction; Primitive reflex; Reflex action; Unconditioned reflex

## Definition

The rooting reflex is the automatic head turning response to the stimulus of face, mouth, or cheek touching.

The rooting reflex is the automatic head turning response to the stimulus of face, mouth, or cheek

touching. Infant apes will involuntarily orient their face toward the stimulation, often the mother's nipple, searching for the stimulating object with an open mouth. During development, the rooting reflex appears in utero, is present at birth, and disappears in early development. It is a primitive reflex present in newborn apes to facilitate feeding via maternal milk secretion. The rooting reflex is related to the suckling reflex, the automatic sucking response to any pressure to the newborn mammal's mouth. The rooting reflex has primarily been studied in humans, although it is evident in other apes including chimpanzees (Salloway 2011).

Primitive reflexes in humans include the step reflex, tonic neck, Palmar grasp, Plantar reflex, Babkin reflex, Galant reflex, the suckling reflex, and the rooting reflex. The rooting reflex in humans normally appears around 28 weeks gestation, is fully developed at 34 weeks gestation, becomes less prominent 1 month after birth, and disappears around 4 months after birth (Sosa et al. 2004). Absence of the rooting reflex in newborns indicates brain stem dysfunction, whereas persistence of the rooting reflex beyond early infancy indicates cortical dysfunction (Sosa et al. 2004). Frontal lobe disorders sometimes produce the reappearance of the rooting reflex in humans later in development (Salloway 2011). The rooting reflex coincides with altriciality, or the inability of young to attain food independently via locomotion. Altricial animals require more parental care for survival than do precocial animals. Precocial mammals are able to root and nurse voluntarily at birth and do not require reflexive responses to secure nutrients.

Primates are a relatively altricial mammalian order, with humans representing a highly altricial species, which can be explained by the metabolic limit hypothesis (Dunsworth et al. 2012). According to this hypothesis, labor and delivery occur when the mother can no longer continue to supply the fetus with metabolic and nutritional requirements in utero. The large brain of the fetus becomes too energetically costly for the mother to continue to supply nutrients in utero and external feeding is more efficient for the mother, creating a tradeoff between prenatal

brain development and maternal energetic expenditure. Birth canal size produces another constraint on gestation duration for a large-brained, metabolically demanding fetus, resulting in earlier labor and delivery than is optimal for brain growth (Ruff 2017). As a result of the increasing metabolic demands of a large-brained fetus, birth occurs when the brain is not fully developed and, therefore, the newborn human is altricial. The rooting reflex, combined with the suckling reflex, solves the adaptive problem of altricial infants having insufficient cerebral capacity to locate and secure nutrients and feed. The rooting reflex is mediated by the brainstem, and as the cerebral cortex develops, the rooting reflex is replaced by voluntary motor functions (Yoo and Mihaila 2020).

Nursing is normally necessary for mammalian infant survival. Maternal milk is dynamic and uniquely suited to the growth and developmental requirements of offspring. Maternal milk contains a high proportion of fats relative to proteins, facilitating newborn brain development (Belfort et al. 2016; Jenness 1979). Operant conditioning facilitates the disappearance of the rooting reflex. Rooting, suckling, and crying serve as infant hunger cues and motivate caregivers to feed newborns. Mothers or caregivers respond to the rooting reflex by nursing, causing the infant to cease display of hunger cues, creating negative reinforcement for the caregiver, and, therefore, motivating feeding as a response to rooting. Nursing in response to the rooting reflex provides positive reinforcement for rooting behavior as an indication of hunger in infants. As infant cerebral cortex development progresses and the rooting reflex disappears, infants continue to root for a period of time as a voluntary indication of hunger (Glodowski et al. 2019).

## Roots and Shoots

Jen Duffy

Jane Goodall's Roots and Shoots Global Committee, The Jane Goodall Institute Global, London, UK

Roots and Shoots, The Jane Goodall Institute of Canada, Toronto, Canada

Jane Goodall's Roots & Shoots is the global humanitarian and environmental education and youth engagement program of the Jane Goodall Institute. It was founded in 1991 by renowned primatologist and conservationist, Dame of the British Empire and United Nations Messenger of Peace, Dr. Jane Goodall, with the mission to:

Foster respect and compassion for all living things, to promote understanding of all cultures and beliefs and to inspire each individual to take action to make the world a better place for people, other animals and our environment.

Roots & Shoots began with 12 Tanzanian high school students who approached Goodall with concerns about local sustainability issues, such as the destruction of the coral reef by illegal dynamiting, poaching in the wildlife parks and reserves, lack of assistance for street children, ill treatment of animals in markets, lack of environmental education, river pollution, and draining the wetlands. Upon Goodall's suggestion and with her support, they formed student groups to raise awareness and take action on these issues. The program now comprises a global network, engaging hundreds of thousands of young people (and the young at heart) in nearly 100 countries on 6 continents.

The central tenet of Roots & Shoots is that every individual matters, makes a difference, and has a role to play in making this world a better place for people, other animals, and the environment we all share. The program asks individuals to choose what kind of difference they want to make and, through the programmatic pillars of knowledge-compassion-action, provides them with opportunities and support to develop and lead local actions that address issues they are

passionate about. Participant outcomes include an increase in awareness, compassion, connection to nature, empowerment, confidence, leadership skills, and understanding of sustainability and volunteerism. Long-term goals include building the knowledge, attitudes, and practices for participants to live and lead more sustainable lifestyles.

The program is adaptable to both formal education systems and nonformal learning settings and has a specific goal of engaging underserved and socioeconomically vulnerable young people. Participants often include individuals, family groups, community groups, homeschools, classrooms, student clubs, whole schools and universities, as well as unique situations such as the group in Boulder County Jail (Holland 2015).

Recent youth-led actions include local projects such as constructing greenhouses with plastic bottles in Argentina, planting a new woodland in the UK, raising awareness about chimpanzee poaching in Tanzania and the Republic of Congo, planting pollinator sanctuaries in the USA, flying giant peace doves in Israel and the Democratic Republic of Congo, building a Medicine Wheel outdoor learning space in Canada, organizing an annual Animal Parade in Taiwan, and assisting refugees in Germany and Greece and global campaigns such as Roots & Shoots Peace Day (Jane Goodall Institute 2017), a September celebration of living in harmony with each other and with nature in honor of the United Nations International Day of Peace, and International Mobile Recycling Day on January 24 to raise awareness about the detrimental effects of conflict minerals such as coltan and encourage recycling of devices that contain them.

In the words of Dr. Goodall, the name Roots & Shoots is symbolic. "Think of a big tree. It starts as a little seed. Pick it up when the first tiny shoot and roots appear. It seems so small, so weak. Yet there is a life force in the seed so powerful that the shoot, to reach the sun, can work through cracks in a brick wall and eventually knock it down. And the roots, to reach the water, can work through rocks and eventually push them aside. See the rocks and walls as all the problems we humans have inflicted on the planet, environmental and social. And you realize Roots & Shoots is about

HOPE. Hundreds and thousands of Roots & Shoots around the world can break through and make this a better world for all” (Jane Goodall Institute 2015 and personal communication).

## r-Reproductive Strategy

Abhishek Singh

Department of Botany, Banaras Hindu University, Varanasi, India

## Definition

r-Reproductive strategy is adopted by r-selected species which is characterized by smaller body size, rapid developmental rate, high reproductive rate or fecundity, early reproduction, smaller offspring, semelparity, and short life span.

## Synonyms

[r-selection](#); [r-Reproductive strategists](#)

## Introduction

Dobzhansky (1950) studied the natural selection in tropical and temperate zones and found a fundamental difference in between. He found that the mortality in temperate zones is independent of density as well as genotype and phenotypes of organisms. It rather depends on the environmental condition. So, selection favors the organisms with high reproduction and growth rate. On the contrary, in tropics where climate is stable, selection favors the organisms with higher competitive ability. Therefore, in tropics organisms tend to produce fewer offspring with slower developmental rate which ultimately leads to improving competitive ability.

Later on MacArthur and Wilson (1967) came up with the idea of r-selected and K-selected species in their book entitled *The Theory of Island Biogeography*. The K denotes the carrying capacity, and r represents the maximal intrinsic growth rate ( $r_{max}$ ). MacArthur and Wilson originally gave their hypothesis with respect to island where the early colonizers are tend to r-selected with higher intrinsic growth rate, while the late colonizers are K-selected with higher competitive ability.

Further, they elaborate their findings to populations other than islands. Fisher, Haldane, and Wright's work already shown that *r* is suitable for the measurement of fitness at low and increasing population densities. MacArthur and Wilson introduced the *K* for measurement of fitness at higher population densities. They further concluded that in unpredictable environment, populations are rapidly decline, so *r*-selected organisms prevails, while in stable environments, the populations will grow to their carrying capacity where *K*-selected organisms will prevail. They also suggest that *r*-selection will lead to "a shorter developmental time, a longer reproductive life, and greater fecundity, in that order of probability." It means fast and high productivity is the outcome of *r*-selection, while efficiency (especially in resource utilization) is the outcome of *K*-selection.

Pianka (1970) published a short note on "*r*- and *K*-selection." He elaborated the *r*/*K* concept in detail and described the connection between *r*- and *K*-selection. In his words "However, it is clear that there are two opposing kinds of selection, which usually have to be compromised. Certainly, no organism is completely "*r*-selected" or completely "*K*-selected," but all must reach some compromise between the two extreme" (p. 592 in Pianka 1970). He further suggests that an *r*-*K* continuum exists in nature and organisms may present at any point in between two end points (*r* and *K*). In his words "The *r*-endpoint represents the quantitative extreme—a perfect ecologic vacuum, with no density effects and no competition. Under this situation, the optimal strategy is to put all possible matter and energy into reproduction, with the smallest practicable amount into each individual offspring, and to produce as many total progeny as possible. Hence *r*-selection leads to high productivity. The *K*-endpoint represents the qualitative extreme—density effects are maximal and the environment is saturated with organism. Competition is keen and the optimal strategy is to channel all available matter and energy into maintenance and the production of a few extremely fit offspring. Replacement is the keynote here. *K*-selection leads to increasing efficiency of utilization of environmental resources" (pp. 592–593 in Pianka 1970).

## Life History of r-Reproductive Strategists

*r*-Reproductive strategists are characterized by several life history attributes such as high reproductive rate (higher fecundity), rapid development, short life span, early reproduction, and semelparity. These life history attributes help the *r*-Reproductive strategists in successful utilization of environmental conditions in their favor. *r*-Reproductive strategy is successfully employed by the organisms present at lower trophic level, e.g., invertebrates (insects and other invertebrates), small rodents, herbaceous plants, small fishes, phytoplanktons, zooplanktons, some amphibians, etc. These organisms are having very short life span and high reproductive rate, and they attain sexual maturity quickly. The characteristics of *r*-Reproductive strategists are listed in Table 1.

## High Reproductive Rate

*r*-Reproductive strategists have higher intrinsic rate of reproduction. Mostly smaller organisms adopt *r*-Reproductive strategy and tend to produce large numbers of offspring. Most of the invertebrate and some vertebrates (amphibians) tend to produce large quantity of eggs. *r*-Reproductive strategists tend to follow exponential growth.

$$\frac{dN}{dT} = r_{\max} N$$

Per capita/individual growth rate in exponential growth remains unchanged, irrespective of the population size. This allows the populations to grow at faster rate as it becomes larger in favorable environmental conditions. When environmental conditions fluctuate, there is a rapid decrease in population observed but onset of favorable environmental conditions; the population grows exponentially (Fig. 1).

## Rapid Development

*r*-Reproductive strategists tend to grow at faster rate to fully utilize the window of favorable

**r-Reproductive Strategy, Table 1** Characteristics of r-Reproductive strategists. (Adopted from Pianka 1970)

**r-Reproductive Strategy, Fig. 1** Growth curve of **r-Reproductive strategists:** r-Reproductive strategists follow exponential growth model at greater extent. The population of r-selected species grows rapidly with maximum growth rate ( $r_{\max}$ ). However, the population size

never reaches to carrying capacity (K) of the environment. Population size varies in time and shows density-independent fluctuation in population size due to change in environmental conditions

environmental conditions, e.g., several species of insects and herbaceous plants grow quickly during monsoon period. The seeds/propagules of ephemeral plants remain dormant during winter and summer season but onset of brief monsoon period, and dormant seeds/propagules germinate and quickly attain sexual maturity. Similar strategy is also adopted by insects, they came out from their hideouts during monsoon and reproduce to give rise a large number of offspring which take advantage of favorable conditions and complete their life cycle.

### Small Body Size

Smaller body size is a recognizable feature of r-Reproductive strategists. Due to lack of competition, r-Reproductive strategists do not need a robust or big body size, so they tend to be smaller. The unpredictable environmental conditions often cause mass mortality, so smaller body size is preferred over larger body size among r-Reproductive strategists.

### Early Reproduction

The r-Reproductive strategists attain sexual maturity early in their life history in order to quickly utilize the environmental opportunity. Due to availability of abundant resources, lack of density-dependent selection, and being opportunistic, r-Reproductive strategists tend to early in their life cycle, e.g., several ephemeral species (mostly insects and plants).

### Semelparity

Most of the r-Reproductive strategists are semelparous in nature, i.e., they reproduce only once in their life time, e.g., several species of r-Reproductive strategists such as many invertebrates including majority of insects, herbaceous plants, etc. However, there are some exceptions like some insects and most r-Reproductive strategists like mammals which are iteroparous (reproduce multiple times in their life history).

## Short Life Span

Since the r-Reproductive strategists have to utilize a brief window of opportunity of favorable environmental conditions, hence, its successful strategy to grow and reproduce quickly. The uncertainty of environmental conditions is a major issue among r-Reproductive strategists as it causes density independent mass mortality which leads to shorter life span. The life span of r-Reproductive strategists varied from few hours to few months.

## Ecological Significance of r-Reproductive Strategy

r-Reproductive strategists are generally opportunistic in terms of resource utilization. In favorable environmental condition, they grow rapidly and tend to utilize maximum resources. However, any fluctuation in favorable environmental conditions (in the form of drought, flood, fire, and thunderstorms) often leads to density-independent mass mortality. Such calamities reduce the population density significantly below the maximum sustainable level of the ecosystem, e.g., sudden burst in populations of herbaceous plants (annual) and insects during spring and summer but rapid decline during winter season. Since, such populations are subjected to regular explosive growth episodes, hence known as opportunistic population. Catastrophic mass mortality in r-Reproductive strategists due to sudden variation in environmental conditions has no/little relation with genotype, phenotype, and population size of the related organisms.

r-Reproductive strategy is generally adopted by the early colonizers during ecological succession of newly formed habitat (Gadgil and Solbrig 1972; Abrahamson and Gadgil 1973; Gaines et al. 1974). Since, pioneer communities inhabiting the newly formed habitat are reach to carrying capacity of the environment. Hence, they rarely deplete their resources to low level as do the organisms present in climax communities. Due to the presence of plentiful resources, the pioneer communities (r-Reproductive strategists) face little or no

competition as compared to intense competition among climax communities (K-reproductive strategists). In the absence of competition, the pioneer communities are able to invest maximal amount of their energy in reproduction and tend to produce large number of offspring. Smaller offspring are energetically efficient to be produced in such environments as the absence of competition allows the growth of even smaller progeny. Hence, the early colonizers are characterized by rapid growth, early maturation, high reproductive rate, and smaller offspring. Such qualities in early colonizers enable to occupy and spread quickly in newly formed habitat.

However, as succession proceeds, the pioneer communities are replaced by more stable seral and climax communities, and the environment becomes more stable. The stable environmental conditions lead to density-dependent selection and thus support the more competitive organisms (r-Reproductive strategists) over less competitive one (K-reproductive strategists).

Although an organism may be either r-strategist or a K-strategist only in comparison with other organisms, e.g., if we compare small rodent mammals such as mouse with insects or microbes, then, ofcourse, it will be a K-strategist, but when we compare it with large mammals such as whales and elephants, then it would be considered as r-strategist. Hence, the determination of r- and K-selection is purely comparative. In nature no organism is completely r-selected or K-selected; rather an r-K continuum exists as earlier suggested by Pianka (1970). The organisms modulate their reproductive strategy according to environmental conditions. Several r-Reproductive strategists shift their habit from r- to K-selection at some extant during the change in environmental conditions. For example, Mueller and coworkers generate r- and K-selected lines of fruit flies (*Drosophila melanogaster*) by breeding the duplicate populations at high and low densities. At lower population densities, r-selected lines developed a high capacity to increase population size while a lower capacity for increase in population size at higher population densities (Mueller and Ayala 1981; Mueller et al. 1991).

Fugitive species are an interesting example of opportunistic species, as they are considered as poor competitor because their dominance is reduced significantly due to interspecific competition, but they tend to dominate in newly formed habitat due to their high dispersal rate (Pianka 2008). Such abilities in a species allow them to persist in patchy environment by continually changing their position despite the presence of highly competitive species. In the case of planktonic species, several species of planktons can coexist in diverse planktonic communities under comparatively uniform physical condition without any apparent ecological separation, also known as “paradox of the plankton” (Hutchinson 1961). This can be explained by the fact that temporal change in environmental conditions may lead to increase in diversity of related planktonic species by changing their competitive ability, thus promoting their coexistence.

## Conclusion

The r-Reproductive strategy is commonly adopted by the opportunistic species. r-Reproductive strategists exploit the resources of newly formed habitat due to their life history characteristics such as rapid development, high  $r_{\max}$ , early reproduction, small body size, semelparity, and short life span. However, any fluctuation in favorable environmental conditions leads to catastrophic density-independent mass mortality among r-selected organisms. During ecological succession, the early colonizers are r-selected, but as the succession proceeds, r-selection organisms are replaced by K-selected. In nature, there is no organism which is completely “r-selected” or “K-selected”; rather an r-K continuum is present. The term r-strategists or K-strategists are relative; it means that if we compare two r-Reproductive strategists, then one will be more r-selected than the other and vice versa for K-reproductive strategists.

## Runaway Selection

Laura M. Travers

Centre for Ecology and Evolution, University of Exeter, Cornwall, WA, UK

## Synonyms

Fisherian selection

## Definition

Runaway selection is a mechanism whereby a secondary sexual trait expressed in one sex becomes genetically correlated with a preference for the trait in the other sex. The genetic coupling of the trait and the preference leads to self-reinforcing loops of coevolution between the trait and preference for the trait. This process is known as runaway selection and can lead to accelerated evolution of exaggerated traits and preferences.

## Introduction

One of the greatest challenges to Darwin's theory of evolution by natural selection was the presence of exaggerated male traits (Darwin 1859). Such traits encompass a wide variety of elaborate visual, acoustic, chemical, and behavioral characteristics (e.g., tail of the peacock or courtship song in birds). These traits appear to contradict Darwin's idea that selection acts on traits that increase survival. Elaborate ornaments and displays seem maladaptive to their bearer as they are costly to maintain (Grafen 1990; Zahavi 1975); they can trade off against investment in other important life history traits such as immune function (Folstad and Karter 1992) and can make

an individual more conspicuous to predators. Why would selection favor traits that incur fitness costs with no obvious fitness benefits? Darwin himself suggested that these traits might evolve through sexual selection, where the bearers benefit from higher reproductive success (Darwin 1871). He proposed that male ornaments could evolve through female choice if females prefer to mate with males sporting exaggerated traits. Thus, the benefit to males gained through sexual selection would offset the costs incurred through natural selection. Since Darwin, female preference and the benefits females accrue from exhibiting preferences have been studied across many taxa. The idea that elaborate male traits evolve via female choice is now widely accepted (Andersson 1994).

Females can increase their reproductive success by mating with males that provide direct and indirect benefits. The expression of a male trait may indicate a male's ability to provide resources. If so, females can increase their fitness directly by mating with males that provide, for instance, bigger nuptial gifts or more paternal care (Arnqvist and Nilsson 2000). In species where males provide no direct benefits, the most commonly invoked mechanism for female preference for exaggerated male traits is indirect (i.e., genetic) benefits (Jennions and Petrie 2000). In this scenario, traits are indicative of male genetic quality, rather than of the ability to provide resources. Therefore, by mating with particular males, females can increase their fitness indirectly because their offspring will inherit genes that increase their fitness (Kirkpatrick and Barton 1997). However, much debate still surrounds the selective mechanisms underlying the origin and maintenance of female preference.

## Fisher's Theory

One mechanism to explain the evolution of female preference was proposed by Ronald A. Fisher. Fisher proposed that a female's preference for a particular male trait could benefit that female indirectly through the production of more attractive offspring (Fisher 1930). According to Fisher's theory, females with a preference for ornamented males will produce sons with higher mating

success due to their inheritance of the extravagant trait from their father. Hence, increased mating success of sons characterizes the indirect benefit of female preference. In addition to sons inheriting the male trait from their fathers, daughters will also inherit the preference for the trait from their mothers. Consequently, genes responsible for the male trait and genes responsible for female preference for the trait become genetically coupled in the offspring. The higher mating success of the ornamented male helps carry the allele for the male trait to higher frequencies. Importantly, it also increases the allele frequency of female preference for the exaggerated trait due to the genetic correlation brought about by assortative mating.

Fisher originally hypothesized that the preferred male trait would initially confer some naturally selected advantage. For example, if tail length in males increases survival, females with the preference for long tails will benefit from producing sons with both a natural and a sexual selection advantage because they are preferred by females (Fisher 1930). However, when the genetic coupling of the trait and preference in the offspring is established, the male trait will eventually become so extreme due to the positive feedback loop between trait and preference that it will no longer carry any naturally selected advantage. At this point, the trait may even be deleterious to survival, so the fitness advantage of the trait exists only because of its covariance with the preference, providing sons with higher mating success.

However, mate preference resulting in the genetic coupling of trait and preference can originate in ways different from natural selection (e.g., sensory bias). Regardless of the initial reason for female preference, a positive feedback mechanism will result in more exaggerated sons and choosier daughters being produced with each successive generation, leading to self-reinforcing loops of coevolution. This will lead to the spread of both the preference and the trait throughout the population. Female preference for more exaggerated male traits is predicted to continue until the cost of carrying the ornament outweighs the benefit of possessing it in terms of mating success.

Note that while in most species females are the choosier sex because of their more substantial reproductive investment, the principles of runaway selection can equally apply to female secondary sexual traits and male preference in sex role-reversed species.

### Postcopulatory Runaway Selection

Until a few decades ago, females were viewed as being fundamentally monogamous. Thus, it was generally assumed that female mate choice only occurred prior to mating. It has since been realized that females in most species mate with multiple partners, which extends sexual selection into the postcopulatory arena. When females' mate multiply (polyandry), sperm from several males can compete for access to the female's ova (sperm competition; Parker 1970). By mating polyandrously, females can exert selection on male traits that increase a male's fertilization success (Simmons 2001). In analogy to precopulatory female preference for exaggerated male secondary sexual traits, females can act as agents of selection on male postcopulatory traits by mating multiply. Hence, Fisherian selection may act on male postcopulatory traits. For instance, the sexy sperm hypothesis posits that female multiple mating can drive the coevolution of polyandry and sperm competition (Keller and Reeve 1995). By inciting sperm competition, polyandrous females will be fertilized by competitively superior males. Thus, sons of polyandrous females will inherit genes for enhanced sperm competitiveness from their fathers, and daughters will inherit polyandry genes from their mothers. This is predicted to generate the coevolution of sperm competitiveness and polyandry through Fisherian runaway selection (Curtisinger 1991; Keller and Reeve 1995).

### Testing Fisher's Model of Runaway Selection

Fisher's theory assumes the presence of heritable variation both in the male trait and female preference for it. It also predicts a genetic correlation between trait and preference through linkage disequilibrium that builds up by assortative mating. However, persistent directional female choice on a male trait should exhaust genetic variation in the

trait and eventually drive the trait to fixation. Once at fixation, there is no genetic variation in males, and female choosiness will no longer be associated with increased mating success in sons. This can create the conundrum where female choice persists despite that choice providing no benefit, the lek paradox (Kirkpatrick and Ryan 1991; Taylor and Williams 1982). Given this paradox, there has been much focus on investigating what maintains heritable variation in male traits despite directional selection from female preference.

Genetic models have examined Fisher's theory (Andersson 1994; Kirkpatrick 1982; Lande 1981; Mead and Arnold 2004), and much empirical work has addressed the assumptions underlying Fisher's mechanism. For the trait and preference to be correlated, a key assumption is the presence of heritable genetic variation in both traits. Empirical evidence supports the existence of ample additive genetic variation in both male attractiveness and female preference (Bakker 1999; Bakker and Pomiankowski 1995; Taylor et al. 2007).

Several studies have found support for the runaway process. In a wild population of three-spined sticklebacks, Bakker (1993) found genetic variation for male redness intensity and female preference for redness in males. He also found a genetic correlation between the red pigmentation in sons and preference for the red coloration in daughters as predicted by Fisher's theory. Other studies have investigated evidence for Fisherian selection in the postcopulatory arena (Lüpold et al. 2016; Simmons and Kotiaho 2007). In the dung beetle, *Onthophagus taurus*, males with short sperm have a fertilization advantage when mating with females that have large sperm storage organs (spermathecae; Simmons and Kotiaho 2007). The authors found heritable variation in both male sperm size and female spermathecae size and a negative genetic correlation between the two (Simmons and Kotiaho 2007). This finding supports Fisherian selection, whereby postcopulatory female choice can shape the evolution of male traits (in this case, sperm size), similar to precopulatory female preference driving the evolution of male secondary sexual traits.

If there is genetic covariation between female preference and secondary sexual male traits, then

artificial selection for an increase or decrease in the male trait should lead to a corresponding shift in female preference. Houde (1994) diverged guppy selection lines by selecting for high and low levels of coloration, respectively. In line with Fisher's prediction, females from lines in which males were selected for increased coloration showed stronger preference for coloration than females from lines selected for decreased coloration.

In contrast to these positive findings, several studies have failed to find support for Fisher's theory. For example, a large-scale quantitative genetic analysis of over 8500 collared flycatchers revealed significant heritable genetic variation in a male ornament and in female mate choice for this ornament but negligible evidence for a genetic correlation between the two (Qvarnström et al. 2006). This suggests that alleles for mate choice had not coevolved with alleles for the ornament as predicted by the runaway theory. Similarly, in a study of a wild-derived population of *Drosophila montana*, Ritchie et al. (2005) found genetic variation in male courtship song and female preference for the song but no covariance across families between the preference and the trait. Moreover, Travers et al. (2016) examined the genetic basis of polyandry and sperm competitiveness in *Drosophila melanogaster* and found little heritability in sperm competitiveness, indicating that Fisherian selection did not drive the coevolution of sperm competitiveness and female multiple mating.

In conclusion, investigation into covariation between male traits and female preference has yielded mixed findings, with many studies finding weak or no genetic correlations between trait and preference (Kirkpatrick and Ryan 1991; Andersson 1994; Bakker and Pomiankowski 1995; Greenfield et al. 2014). A review on within-population preference and trait coevolution found overall weak levels of covariance (Greenfield et al. 2014), which suggests either that runaway selection plays a marginal role in the evolution of female preference and/or that measuring the strength of runaway selection is empirically challenging.

## Challenges and Future Directions

Given the contradictory findings thus far, the role of runaway selection in promoting the coevolution of male traits and female preferences remains unclear. A number of factors may have contributed to producing conflicting findings.

In Fisher's theory, linkage disequilibrium, the genetic covariation between male trait and female preference, accumulates by assortative mating; females with preferences for exaggerated traits mate and produce offspring with males bearing those traits (Fisher 1930; Lande 1981). Because the genetic covariance by linkage disequilibrium is established and maintained by assortative mating rather than physical linkage, linkage disequilibrium can break down rapidly (by 50% per generation) when assortative mating ceases (Bakker 1999; Bakker and Pomiankowski 1995). Thus, the genetic covariation can be lost in just a few generations. Many have highlighted that experimental conditions in the laboratory have the potential to disrupt assortative mating and hence break down the genetic correlation between female preference and male traits. For example, many quantitative genetic studies impose random mating in the parental generation to uncouple maternal and environmental effects from genetic parameters. This can break down linkage disequilibrium and result in the failure to detect the genetic correlation between trait and preference (Bakker and Pomiankowski 1995). Studies in wild populations could overcome this limitation, as could experiments performed within the first generations of laboratory breeding.

A second issue is whether studies that have investigated Fisher's theory had sufficient statistical power to detect the genetic covariance. Simulations by Sharma et al. (2016) indicate that the sample size needed to confidently detect trait-preference genetic correlations is much larger than those reported in studies thus far. Therefore, it may not be possible to appropriately gauge the importance of runaway selection in natural populations until more studies with large sample sizes are conducted.

Finally, little is known about the nature of female mating preference. Most studies that have investigated trait-preference coevolution have focused on measuring the relationship between

the expression of a single trait in males and female preference for that trait in isolation. However, several traits contribute to a male's overall attractiveness, and females are likely to choose males based on multiple traits (Prokop and Drobniak 2016). The heritability of overall attractiveness will typically be lower than the heritability of any individual trait. Thus, to assess the strength of Fisherian selection, one must quantify the benefit to the female through her sons' mating success, rather than the value of a single trait. Explicit measures of male mating success will prove useful for understanding the fitness consequences of female choice.

## Conclusion

Darwin first proposed mate choice as an explanation for the evolution of elaborate behavioral displays and morphological traits in males. Fisher's runaway process has become a central theory to the investigation of the evolution and maintenance of mate choice and exaggerated male traits. Its theoretical importance has led to intense theoretical and empirical testing of the theory's assumptions. Yet, our understanding of mate choice and the role of Fisherian selection in driving male traits beyond their naturally selected optima remains limited. Much interest remains in this potentially pervasive explanation of how selection on males and females leads to the stunning and often bizarre traits we observe in nature.

## Rutting

Bonner Powell and Kristine O. Evans  
Department of Wildlife, Fisheries and  
Aquaculture, Mississippi State University,  
Mississippi State, MS, USA

## Synonyms

Musth; Rutting period; Tugging

## Definition

The periodically recurring sexual excitement of mammalian species including cervids (e.g., deer, sheep, goats), elephants, and other mammals.

## Introduction

The term rutting (i.e., the behavior of mammals during the rut) is derived from the Latin word “*rugire*,” meaning to roar. This phenomenon occurs in deer, goats, sheep, camels, bison, moose, elephants, and several other mammals and is particularly evident in species of the Cervidae family. Due to changes in photoperiod, hormones in animals fluctuate, resulting in increased testosterone levels in males and triggering onset of rutting behavior. Similarly, increases in estrogen and other hormones in females triggers onset of estrous in many species. Increased testosterone levels increases male aggression during peak rutting times, which coincides and sometimes releases estrous in females of rutting species.

During non-breeding periods males of some rutting species can be found in bachelor groups, which consist of several males that travel and live together. Prior to and during onset of rut, levels of aggression rise and bachelor groups separate. Males of many rutting species become intolerant of other males and often engage in direct conflict or make displays of dominance toward other males. Some species of mammals have intense displays of aggression which reduces the amount of direct conflict in these species. Fighting in males during the rut is a tradeoff (Geist 1964). The animals risk injury and death for the opportunity to pass on their genes. Some males practice conflict avoidance to reduce the risk of injury. In some species, such as white-tailed deer (*Odocoileus virginianus*), necks of males will swell to increase apparent body size. White-tailed deer bucks will also lock antlers and spar with one another until one of the males submits to the more dominant individual.

Vocalizations are another indicator of rutting behavior in several different species, and are used during the rut to demonstrate dominance among

males and to attract females into an area. Male elk (*Cervus canadensis*) are often observed and heard bugling during rut – this behavior is best described as a low growl that turns almost into a whistle. Hangul deer (*Cervus elaphus*) males are also often observed roaring during the rut (Bhat et al. 2009).

Male African elephants (*Loxodonta africana*) exhibit two indicative signs that they are in musth (i.e., a period of surging testosterone levels in elephants akin to rut in cervids). Temporal gland secretion can be seen on the side of the forehead of elephants in musth and is distinguished by a wet line that is running down their face. The second sign is urine dribbling. A rise in aggression also accompanies these two visual signs when elephants are in musth (Ganswindt et al. 2004). Males will also utilize scent-marking as a means to attract females and display dominance in an area.

White-tailed deer bucks make scrapes in the dirt with their hooves, and then eliminate to leave their scent in an area (Pruitt 1954). They also frequently make rubs that coincide with scrapes by peeling bark from small diameter trees and limbs with their antlers. Moose (*Alces alces*) also exhibit rubbing during rut. They can extensively damage small trees by removing the bark up to 7 f. high on the trunk. Rubbing is thought to leave scent on marked trees as well as provide a visual sign to females and other males.

The initiation of the rut is commonly triggered by photoperiod during the season. Photoperiod, or daylength, is the period of time each day that illumination, or solar light, is available to an organism. When the days shorten, changes to circadian rhythms in the body trigger hormone release and/or suppression, causing behavioral and physiological changes that prepare the individual for breeding. Female deer, commonly referred to as does, come into estrous due to a combination of photoperiod-linked releases and other factors (Murphy et al. 1994). Does remain in estrous for only about 24 h, and if not bred will go out of estrous. They then begin a 21–27 day cycle to return into estrous, which is repeated up to four times during a breeding season (Knox et al. 1988). This recurring estrous cycle in females can contribute to the late breeding reports that are sometimes received. This

is important because the estrous cycle can determine how long males rut. Males will continue to breed until they cannot find any females that are in estrous or until they are too exhausted energetically to breed.

## Conclusion

Onset of rutting is triggered by photoperiod in white-tailed deer, elk, moose, and several other species. During these times, males become more aggressive and start to show strange behaviors related to pursuit of females in estrous. During the rut, male deer, moose, elk, elephants, and other species will also expand their home range to increase opportunities for breeding with a greater number of females. They may also pursue females to great lengths and expend a tremendous amount of energy while in pursuit.

### Introduction

Animal vision is incomplete without the ability to change the gaze that involves coordinated control of eyes, head, and body movements (McCluskey and Cullen 2007). Saccadic eye movement is one of the mechanisms by which an animal redirects the gaze. As opposed to smooth pursuit movement that helps in tracking a moving object, saccades consist of a rapid ballistic movement of both the eyes from one point of fixation to another. Thus saccades require rapid movement of eyes to new location followed by fixation and inhibition of further eye movement. The orienting eye movement is achieved by the oculomotor system in the brain (Enderle 2002). However, saccadic gaze can be

achieved even in a case of congenital eye muscle paralysis by similar saccadic movements of the head (Gilchrist et al. 1997). Thus, saccadic gaze is an integral part of the visual system. The term “saccade” (jerk) was first used by a French ophthalmologist Louis Émile Javal. However, research on saccadic eye movements was initiated even before the popularity of this terminology. The first appearance of saccade-like movement in animal kingdom is seen in fish where the role of these eye movements was to re-center eye direction whenever the animal turns. However, with evolution the main function of saccades became to position the fovea (part of the retina with where vision is most precise) onto the object/s of interest. In humans, the direction, duration, and destination of the saccades are selected by the cognitive brain processes that often occur without conscious awareness (Walker et al. 2000). Thus, study of saccadic eye movements can help us in understanding the brain processes during cognitive tasks.

### Neural Substrate of Saccadic Eye Movement

As mentioned earlier saccadic eye movements are mediated by the neurons in the oculomotor system that includes nuclei of III, IV, and VI cranial nerves. Moreover, neurons of brainstem, superior colliculus, frontal eye field, supplementary eye field, basal ganglia, cerebellum, and frontal and

parietal association areas are involved in saccadic eye movement (Enderle 2002). High-frequency burst of the oculomotor neurons innervating the extraocular muscles overcomes the inertial forces to initiate the saccades. The direction of the eye movement is controlled by two gaze centers, viz., paramedian pontine reticular formation for horizontal gaze and rostral interstitial nucleus for vertical gaze. Frontal eye field (FEF) receives input from the extrastriate cortex for initiating stimulus-driven saccades. The sequential planning, execution, and learning of saccades are done by FEF via coordination with the basal ganglia and cerebellar neuronal circuitry. Higher-level planning of saccades is done by prefrontal cortex, while information related to the spatial coordinates provided by the associative parietal areas. Visual stability during saccades that prevents blurring of vision even though there is movement of the image on the retina is known as saccadic suppression. Saccadic suppression is possible at high-contrast visual conditions with the help of visual masking which involves neuronal suppression of primary visual cortical neurons (Bremmer et al. 2009), while saccadic suppression in low-contrast conditions is mainly by corollary discharge that suppresses the magnocellular pathway in lateral geniculate nucleus and motion-related areas in middle temporal and medial superior temporal cortices (Bremmer et al. 2009).

## Recording Paradigms and Types of Saccades

One of the earliest methods of recording saccades was using contact lens optical lever that could record eye movement in seconds arc (Kowler 2011). Later studies were done using magnetic-field/search-coil method that was more precise and could record three-dimensional eye movements (Eggert 2007). However, both the techniques were invasive. Electrooculography (EOG) is one of the commonest techniques used in present day to record eye movements (Eggert 2007). The principle behind this technique is that each eye acts as a dipole with retina relatively

negative as compared to the cornea. The direction of this dipole is almost the same as the direction of the visual axis. Moreover, the dipole moves along with the movement of the eyes. Using surface electrodes, the movement of the dipole can be tracked to record horizontal or vertical eye movements. Another common technique used to record eye movement is using infrared reflective devices that track the eyes by measuring the intensity of infrared light reflected from the eye at fixed locations close to the eye. These devices require regular calibration in order to maintain the accuracy and cannot record torsional eye movements. With the recent advances in digital processing, video-oculography (VOG) has gained popularity in recording eye movements (Larrazabal et al. 2019). This technique uses pupil, iris, and other head-fixed markers to track the movement of the eyes and can even record torsional eye movements.

Saccades can be classified based on the type of stimulus that initiates them. Reflexive saccades are peripheral stimulus-driven bottom-up responses, while voluntary saccades are endogenous stimulus-driven top-down responses (Walker et al. 2000). The prefrontal lobe dysfunction seen in schizophrenia leads to decreased ability to inhibit reflexive saccades and decreased ability to produce voluntary saccades when required (Enderle 2002). Saccades are typically stereotypic ballistic movements, and thus each saccade shows similar patterns. Nevertheless, various parameters are used to study saccadic eyes movement. Saccadic latency is the time taken for saccade initiation from the presentation of the stimulus. This latency depends on the time taken for the impulse to travel along the afferent and efferent pathway including central processing time. Saccade amplitude or size and saccadic duration are nonlinearly related to each other, while saccadic velocity linearly correlates with saccadic size. Slow (decreased velocity) hypometric (decreased size) saccades are seen in spinocerebellar degeneration (Geiner et al. 2008). Probable cause of slow saccades seen in spinocerebellar ataxia type 2 is degeneration of excitatory burst neurons of the brainstem (Geiner et al. 2008). A type of voluntary saccades in which

the timing and position of the stimulus can be predicted is called anticipatory saccade (Pfeuffer et al. 2016). Anticipatory saccades are markers of learning during sequential procedural cognitive task (Pfeuffer et al. 2016). A task in which the participant is instructed to delay the saccade by increasing the duration of fixation stimulus produces delayed saccades which can help in understanding the mechanism involved in inhibition of saccades. Frontal eye field inhibition that diminishes the superior colliculus activity forms one of the mechanisms by which delay in saccades is produced (Enderle 2002). Even during eye fixation tasks, small dynamically continuous miniature eye movements are seen called microsaccades. The function of microsaccades is to maintain a continuous visual perception and prevent perceptual fading (Rolfs 2009).

## Sacred Cats

Noreen Doyle  
University of Arizona Egyptian Expedition,  
Tucson, AZ, USA

## Synonyms

Feline cult; Felines in religious ritual; Temple cats

## Introduction

Through their appearance and behavior, animals have always provided visual imagery, metaphors, and materiel through which a culture may express its ideas about – and interact with – the “divine” (Wilkinson 2003; Guthrie 2005; Counts and Arnold 2010; Allen 2016). In religious and other cultural contexts, animals are not only sources but also recipients; the often complex and contradictory symbolic functions assigned by a human society to a nonhuman species shape human interactions with these other animals (Engels 1999; Lawrence 2003). Felines have played simultaneously conflicting roles as antagonist and as guardian probably since Paleolithic times, if not earlier (Saunders 1991; Allsen 2006). Early humans (genus *Homo*) and their ancestors competed with big cats (subfamily Pantherinae) for living space and for prey, such as deer, tapir, and

cattle (Saunders 1998). Big cats posed a predatory threat to hominins, but also served as providers of kills that could be scavenged.

The oldest surviving evidence of a feline in a culturally meaningful role is the figural art of *Homo sapiens* during the Upper Paleolithic (beginning about 38,000 BCE), a period when animals dominated the visual repertoire (Guthrie 2005; Fig. 1). Relative to images of herbivorous prey species, images of cats and other carnivores are uncommon for this period (Saunders 1991). The lions of European Upper Paleolithic art are *Felis leo* or a close relative. The lack of manes in most representations suggests that the artists were portraying lionesses, but even those that do have manes sport only scanty ones, so male lions in these times and places might not have grown the magnificent manes that characterize the animals at later periods (Guthrie 2005). Short strokes protruding from the nose of one of the Lascaux lions have been interpreted as either blood pouring from a wounded animal or the animal's breath, either as an indication of fury or the power of its life (Guthrie 2005).

Necessity may have driven early humans to become keen and close observers of these predators (Guthrie 2005). Still, some scholars attribute the relatively crude rendering of cats in some Paleolithic cave art (such as at Lascaux, France),

which contrasts with sensitive, well-observed renderings of bison and other prey animals, to the danger of viewing the predators up close (Saunders 1991). Chauvet Cave, also in France (c. 35,000–29,500 BCE), features surprisingly abundant and realistic heads of lions. That the Chauvet lions include the detail of whisker spots on the muzzles suggests that the differences between these lions and those at Lascaux may result from “inexperienced drawers” rather than inexperienced observers (Guthrie 2005), but greater realism does not lead to greater understanding of the meaning or motive of the artists.

### Big Cats (Pantherinae)

Symbolisms that later cultures assigned to big felines are better understood. While varied, these share some common themes. Through image, word, and/or parts of the animal, powers of dangerous animals – scorpions and snakes, for example – are commonly coopted for use in apotropaic (protective) rituals performed either by individuals or by the state. Big cats (particularly the lion [*Panthera leo*], leopard [*P. pardus*], tiger, [*P. tigris*], jaguar [*P. onca*], and puma [*P. concolor*]) have commonly been adopted as emblems of the governing class and other powerful social strata (McCall 1973–1974; Zuidema 1983; Malek 1993; Saunders 1991, 1998; Counts and Arnold 2010; Sugiyama et al. 2013). Through the use of feline skins, fur, claws, teeth, bones, and flesh, kings, warriors, and shamans have sought to acquire ferocity, strength, vision, and other feline traits deemed desirable (McCall 1973–1974; Zuidema 1983; Saunders 1998; Sugiyama et al. 2013).

Despite their generally nocturnal habits, members of the subfamily Pantherinae commonly acquire solar associations. This might be due to the tapetum lucidum, a brightly reflective layer of cells behind the retina of the eye that gives cats their superb night vision (Saunders 1988). In some cultures, the yellow color of a cat's coat might be specifically cited as a reason to affiliate the animal with the sun (Saunders 1998). The ancient Egyptians had several solar lion deities.

**Sacred Cats, Fig. 1** Felines of uncertain symbolic significance to Paleolithic humans: Drawings of lions in Chauvet-Pont-d’Arc Cave, France, c. 35,000–29,500 BCE

Most of the leonine goddesses (Sekhmet, Bastet, Tefnut, and Mut, among others) were viewed as the dangerous and vengeful Eye of the sun god, Re, who was depicted most often as a falcon (typically the peregrine falcon, *Falco peregrinus*) but also on occasion as a smaller cat species (see Felinae, below). Another Egyptian goddess often shown as a large feline, Mafdet, guarded the sun from the divine serpents that attempted to thwart the sunrise. Perhaps inspired by the care lionesses give their cubs, ancient Egyptian religious texts refer to these fierce goddesses in maternal roles. They conceived, birthed, and nursed the king, who was called the “son of the sun” (Delvaux and Warembo 1991; Wilkinson 2003).

The Egyptians symbolized distant regions with lions, which inhabited the arid regions beyond the fertile agricultural land of the Nile Valley. In their temples, the leonine goddesses were appeased with waterways (*isheru*) intended to mimic the natural pools that formed at the edge of the desert as the groundwater rose with the Nile River’s annual inundation, believed to herald the return of the Eye of Re (Delvaux and Warembo 1991). The Egyptians visualized the eastern and western horizons, where the sun rose from and set into the underworld, as two lions either seated or joined

back to back (Wilkinson 2003). Liminal associations, dusk/dawn and the interface between the world of the living and the realm of the dead, appear in Mesoamerican sources as well. The crepuscular and nocturnal habits of jaguars, and their spotted coats, identified these cats with the morning and evening stars (Venus), nighttime aspects of the sky, and the chthonic “Night Sun” of the underworld (Saunders 1998; Latsanopoulos 2008; Sugiyama et al. 2013, 2015).

The arboreal hunting habits of the jaguar further linked it in Mesoamerican symbolism with the sky and high places, such as the tops of buildings. Its affinity for water – unusual for a felid – gave rise to the Water Lily Jaguar (Fig. 2), one of several jaguar deities of the Maya underworld, which, it was believed, could be reached through cenotes (sinkholes filled with groundwater). Among the Shipibo, Waiwai, and Wayana of South America, although the Yellow Jaguar is a solar animal, the Black Jaguar (i.e., melanistic) is a creature of earthquakes, rain, and dangerous manifestations of water (Saunders 1998).

As wild animals, and particularly as predators perceived as threatening human life and livelihood, big cats were also appointed as embodiments of the more generalized natural world

**Sacred Cats, Fig. 2** Feline signifying liminal regions: The Maya god Water Lily Jaguar, dancing in an aquatic environment, with a scarf around his neck that

that existed beyond the boundaries of human settlements and agricultural land. Lions and other Pantherinae appear occasionally in the “master/mistress of animals” motif found in the art of cultures throughout the Old World, although herbivores are far more common (Childs-Johnson 1998; Counts and Arnold 2010). This motif features a human figure grasping or otherwise dominating one or more wild animals to visually express conceptual divisions in religion, politics, and other systems within the culture that created it. Typical examples are dualities of order and chaos, mortal and divine, and life and death. Viewed through such cultural lenses, predatory felines become aggressors that threaten not only livestock but also human social order and wellbeing (Counts and Arnold 2010).

This metaphor was not merely an artistic motif. Ritualized hunts for big cats and other dangerous game allowed rulers to display their dominance over the natural world for political and ceremonial ends; in many cultures, these became royal obligations above and beyond mere sport (Allsen 2006; Weissert 1997). Shang Dynasty kings of China (c. sixteenth to mid-eleventh centuries BCE) hunted tigers for sacrifice. This was an act of legitimation, demonstrating the king’s physical prowess as “master of the hunt” and his ability to propitiate the spirits of the royal ancestors. Oracle bones (bovine scapulae or underparts of turtle

shells, heated to produce cracks that were then interpreted to answer questions) might determine the time, place, and purpose of the hunt and subsequent sacrifice. Most often, the tiger (or other religiously significant animal) was captured alive, to be later shot with an arrow near the ancestral temple (Childs-Johnson 1998).

Assyrian sources (seventh century BCE) present a similar duality of field and urban lion kills with a different overt symbolism (Fig. 3). Field hunts were undertaken under the pretext that an incursion of lions had begun to prey upon even penned livestock. At sunrise, the king mounted a chariot and, within a conventionalized span of “forty minutes,” shot all of the lions. One urban hunt was undertaken at Nineveh (modern Mosul, Iraq) in a place dedicated to the goddess Ishtar. Overlooked by a hill where spectators could gather to witness the spectacle performed specifically for their benefit, the area was cordoned off by armed men. Eighteen lions – one for each gate of the city – were released from cages for the king to shoot from his chariot. When necessary and/or to emphasize the king’s heroism, during these confined hunts some lions were killed with sword or spear. Slain lions were accorded the same treatment as defeated human enemies in a public ceremony of triumph, being presented with food offerings as the king poured a libation of wine upon their heads. Evidence suggests that

**Sacred Cats, Fig. 3** Felines representing forces of chaos: Assyrian royal lion hunt. Nimrud, ninth century BCE. Original in the British Museum, WA 124534 (Line drawing after: Morey 1903)

lion hunts took place near the end of the year to ritually secure the safety of the herds during the coming year. By defeating lions that embodied divine forces of chaos and evil, which made them allies of the primordial goddess Tiamat, the king played the part of a war deity, either Ishtar or her father, Ashur (Weissert 1997).

One text stressed that each caged lion was “of its plain,” that is, wild, although whether this is true remains open to question (Weissert 1997). Ashurbanipal boasted of having captured fifteen full-grown lions and fifty cubs, which he brought to Nimrud (near Mosul, Iraq) and bred. His zoological collection in this city also included tigers and leopards, among other wild animals, as elements of political propaganda demonstrating his mastery of the world (Allsen 2006).

The Egyptians maintained lions in captivity as well, including in specifically religious contexts. In the first century BCE, the Greek historian Diodorus Siculus recorded that Leontopolis (“Lion City”) in the Nile Delta (modern Tell el-Yehudiya) kept a lion in its sacred enclosure, well cared for and fed with great number of live birds (Book I.84.4–5). This animal served as an embodiment of one of Egypt’s leonine deities, Bastet’s son Mahes (Wilkinson 2003).

Particularly in Egypt and Mesoamerica, archeological sites have revealed physical details regarding the capture and keeping of wild felines, both Pantherinae and Felinae. Animal burials dating to the Egyptian Predynastic Period (specifically Naqada IC–IIB; c. c. 3750–3550 BCE) excavated in cemetery HK6 at Hierakonopolis in southern Egypt included the remains of a single large cat – a large male leopard (*F. pardus*) – dated likely to Naqada IIA–B. Placement of its burial and those of other wild species found thus far at this site (e.g., aurochs, *Bos primigenius*; hippopotamus, *Hippopotamus amphibius*; crocodiles, *Crocodylus niloticus*) suggest that they functioned as guardians for the elite human burials in HK6 or as expressions of human mastery over the forces of chaos. While young, the leopard had experienced a pelvic injury, perhaps from a fall. This had healed. Because the animal was elderly at the time of its death, the injury had likely happened long before its capture. The discovery of bones of a

newborn piglet with evidence of digestion suggest that this was its last meal. The manner of the leopard’s death is unknown, but its body was treated with care, being covered with a woven textile and mat before the grave was filled (Van Neer et al. 2013, 2017). Seven or more young leopards – until recently identified as lions – between the ages of six to 12 months, were found at the tomb complex of Aha, one of Egypt’s earliest kings (c. 3100 BCE), at Abydos, also in southern Egypt. Their scattered and incomplete skeletal remains evidenced deformities (rickets-like curvature; missing dentition) indicating that these animals had lived most of their lives in captivity and may have even been born there, perhaps in a royal menagerie (Flores 2003; Van Neer et al. 2013).

Another large feline that had spent considerable time in captivity in Egypt was a very large adult male lion found in a Ptolemaic/Roman-era context (333 BCE–fifth century CE) at Saqqara. It had, however, evidently been taken as an adult or nearly adult, a conclusion drawn from the generally good health of its bones. This animal, too, had evidently suffered a fall with resulting injuries to its vertebrae and ribs. These healed, and the animal appears to have been cared for thereafter, presumably in a temple context, but its diet may have been based on bread that had a heavy inclusion of sand (which was typical of Egyptian bread in antiquity). This resulted in considerable wearing of the teeth, a condition initial examination had attributed to gnawing. The lion lived to the age of about nine, died a natural death, and was mummified and placed in a human tomb that had been repurposed as a Bubastaeion (or Bubasteum), a burial place for mummified sacred cats (Callou et al. 2011; Zivie and Lichtenberg 2003; Ikram 2005).

An incident of Pantherinae burial at Teotihuacan, Mexico, was quite different. There, as elsewhere in Mesoamerica, creation or expansion of architectural monuments occasioned the depositing of offerings selected and arranged with symbolic significance related to the state and its ruling elite. In the third century CE, one of the episodes of enlargement of the Moon Pyramid occasioned an elaborate burial that included

an array of mammals, birds, and a reptile. Two Pantherinae species were represented, puma and jaguar. Some of the deposited felines were merely skulls from animals that had been skinned and defleshed. Others, with their legs bound, had been buried alive. Analyses of bones and stomach contents of some of the complete individuals indicate a varied history. Some had evidently been captured from the wild not long before their sacrifice. One of the pumas, a female approximately a year and a half old, was evidently held in captivity for a much longer period of time than the others. Perhaps during its capture in the wild, it had suffered several injuries, including one to the pelvic region that would have been fatal without human intervention. The state of the animal's teeth indicates that it had chewed on something, perhaps the wooden bars of a cage, for a prolonged time. Its last meal was a pair of young desert cottontails, one of which had signs of having been cooked, indicating that the cat had been fed by humans before being buried alive (Sugiyama et al. 2013). While rabbits (and similar animals) were the typical last meal for these captive cats, chemical analysis of the bones revealed that two of the pumas had also been fed omnivores, perhaps the flesh of domestic dogs or even humans. Mesoamerican art and Spanish accounts of the Aztecs more than a 1000 years later attest to the practice of feeding human flesh to captive carnivores (Sugiyama et al. 2015).

### Small Cats (Felinae)

Smaller feline species also acquired significance in human symbolic systems, although during antiquity only in Egypt did any Felinae achieve the prominence of the lion, jaguar, and other Pantherinae. Posing no threat to livestock, the presence of smaller cat species – for example, the wildcat, *F. sylvestris*, in Africa, Asia, and Europe, and the ocelot, *Leopardus pardalis*, in South and Central America – may have been encouraged by humans for control of commensal undesired species: the rodents attracted by stored food or waste, and the snakes attracted by the rodents. By the eighth millennium BCE, humans

had deliberately introduced the wildcat to the island of Cyprus, perhaps to control the house mouse (*Mus musculus*) that had also arrived with humans. The Neolithic site at Shillourokambos, Cyprus, has yielded the earliest known human burial of a feline, an 8-month-old male African wildcat (*Felis sylvestris lybica*) deposited in its own grave beside that of a young man. The excavators concluded that the wildcat served no religious purpose but had been, nonetheless, very likely killed in order to be included in the human burial (Le Mort et al. 2008).

An unidentified small cat (*Felis* sp.), presumably not domestic because of the age of the grave (Badarian, fifth millennium BCE), was found interred with a human and gazelle at Mostagedda, Egypt (Flores 2003). At cemetery HK6 at Hierakonpolis, in the early Naqada II period (c. 3700–3600 BCE), a young jungle cat (*Felis chaus*) was included in a grave with several anubis baboons (*Papio anubis*) and a very young hippopotamus (*Hippopotamus amphibius*). Between six to 8 months of age at the time of its death, the cat had already suffered at least one, and possibly two, episodes of trauma, likely during or after capture. Its survival for a period of 4–6 weeks, during which the bones healed, is attributed to human care. Its burial may have served the same function as that of the leopard interred at the site at a much later date, as a guardian and/or as an expression of subjugated chaos/nature. At about this same time, also in cemetery HK6, six young wildcats (*F. sylvestris*) were buried together. Their remains showed no sign of trauma or other pathology. The ages of the individual cats (two 7–12 months; four 4–5 months), which were buried simultaneously, suggest that the Egyptians may have been keeping and rearing tamed wildcats for pest control. These may even have been fully domesticated (Flores 2003; Van Neer et al. 2014, 2017).

Although a number of small cat species in both the Old and New Worlds are tamable, whether they possess other traits (exaptations) that would make each seemingly amenable to domestication (Cameron-Beaumont et al. 2002) or not (Ottoni et al. 2017) remains an open question. Among felines, only the commensal relationship between

*F. sylvestris*, the wildcat, and human developed into domestication, resulting in *F. catus* (or *F. sylvestris catus*) (Ottoni et al. 2017). This is the species most frequently thought of as a “sacred cat.” Paleogenetic analysis has demonstrated that domestic cats from Egypt contributed significantly to the populations elsewhere in the world of late antiquity (1st millennium CE), perhaps because it possessed behavioral traits that were exceptionally suitable for its interactions with humans (Ottoni et al. 2017).

By the Middle Kingdom (c. 2030–1640 BCE), and possibly earlier, domestic cats had acquired symbolic value as protective predators, as had their Pantherinae relatives. Cat deities were among the many protectors of the sun god Re as he traveled through the underworld at night (Delvaux and Warembo 1991; Malek 1993). Re himself was sometimes described as the “Great Cat” who slew his own foes. Re’s chief opponent was the great serpent of chaos, Apep, and in vignettes of spell 17 of the Egyptian Book of the Dead, a small cat – sometimes identifiable by its spotted coat as a serval, *Felis serval* – beheads the snake with a knife (Fig. 4; Delvaux and Warembo 1991; Malek 1993). These texts are of New Kingdom date (c. 1550–1070 BCE) and, in this same

period, plays on words led to equations between a female cat (in Egyptian, *miit*) and the goddesses Mut (“mother”) and Maat (“cosmic/social order”).

The strongest and best known of such leonine goddess/domestic cat associations was that of Bastet. This probably transpired sometime in the Twenty-second Dynasty (c. 945–712 BCE), but may have begun earlier. The Egyptians had long viewed Bastet as a less ferocious counterpart of Sekhmet, the goddess of war, disease, and healing (Delvaux and Warembo 1991; Malek 1993; Wilkinson 2003). The fertility of the domestic cat may have inspired the appearance of cat motifs on ritual objects and other contexts related to with Hathor, a goddess of human sexuality (Delvaux and Warembo 1991; Malek 1993). Human fertility and the survival of children was a concern in ancient times, and the nurturing, prolific domestic cat provided an attractive image of a divine force that might render aid in these matters (Fig. 5; Engels 1999).

Since the beginning of the pharaonic era (c. 3100 BCE), the Egyptians had singled out individual animals to serve as manifestations of particular gods. Not viewed as gods themselves, these animals functioned as living counterparts of

**Sacred Cats, Fig. 4** Feline predatory skills against snakes used to symbolize the defeat of chaos: The sun god Re as a cat slaying the serpent Apep. Facsimile drawing by Charles K. the inanimate cult statues kept by every temple. Animal or image provided a medium through which to reach the divine, not only for oracles but to satisfy and appease the gods by means of regular cultic attention. The lion of Leontopolis reported by Diodorus Siculus would have been such a divine representative on earth, but otherwise virtually nothing is known of specific sacred felines. The most ancient sacred animal, and one of the best attested, was the Apis bull, which embodied the divine power of the creator god Ptah in the city of Memphis. Evidence for the Mnevis bull, sacred to the sun god, and ram of Mendes (a sheep, *Ovis aries longipes*, dedicated to the sun and to Osiris, god of the dead) is nearly as old. There was a series of each of these animals, a new one being chosen upon the death of the old, which was mummified and entombed. The Apis bulls were identified by special markings, the particulars of which changed with time. The selected animal was brought to the sacred precinct of the god with great fanfare and lived out its life in luxury (Ikram 2005).

The popularity of this kind of animal cult escalated in the late phases of ancient Egyptian history. From the Late Period (c. 712–332 BCE) until Christian times, Egypt experienced lengthy episodes of foreign rule, culminating with that of the Greeks and, eventually, the Romans. The distinctively Egyptian animal cults, which were viewed with varying degrees of negativity by neighboring contemporaries, may have been attempts to solidify an “Egyptian” cultural identity (Ikram 2005; Bleiberg et al. 2013). They may have also been attempts to return to what was perceived as the traditional cults of earlier, “better” periods. This would, it was hoped, appease the gods who would consequently restore Egypt’s former glory (Ikram 2005). The Greeks who ruled Egypt after its conquest by Alexander the Great sponsored the animal cults as part of their own attempt to legitimize themselves as successors of the native Egyptian pharaohs (Bleiberg et al. 2013).

Sacred cats may have existed earlier in the pharaonic period. At Abydos, during the Twelfth Dynasty (c. 1981–1802 BCE), seventeen cats and ceramic pots that the excavator presumed had contained milk were placed in a small pyramidal

tomb (Malek 1993). Whether these were sacred animals is unknown. Stelae (monumental slabs) from the workman’s village Deir el-Medina (near Luxor, Egypt), dating to the Nineteenth and Twentieth Dynasties (1295–1070 BCE), show individuals venerating divine cats called “peaceful,” “perfect,” or “great.” Whether these were sacred – that is, living – cats or simply depictions of deities in feline form is likewise unknown (Malek 1993).

Whatever motivated the animal cults in later times, they resulted in the keeping and breeding of vast numbers of sacred animals of many taxa until the fourth and fifth centuries CE, when the Christian Roman emperors abolished pagan worship. Among them were crocodiles, birds (especially ibises and raptors), primates (especially baboons), domestic dogs, and a variety of small felines (Ikram 2005; McKnight 2010; Bleiberg et al. 2013). The cats served as the sacred animals of Bastet above all, but, in the symbolic entanglement of big and small cats, they also functioned for other goddesses whose primary association remained the lion, which was not so readily manageable in captivity. In the fourth century BCE, a man named Padikem was “prophet of the living cat of the temple of (the lion goddess) Pakhet” at Hermopolis, in Middle Egypt, site of a large animal mummy necropolis (Malek 1993). Such cult centers existed throughout the country, including major ones at Bubastis in the Nile Delta, at Saqqara (near modern Cairo), and, in Middle Egypt, at Tuna el-Gebel and Speos Artemidos (Delvaux and Waremboel 1991; Ikram 2005). At such places, devout individuals came to make offerings to the god or goddess or to solicit an oracle in which the sacred animal may have played some role (Ikram 2005).

Foreign and Egyptian textual sources, as well as the excavated remains of the animals, offer hints regarding the management of the sacred cats. Temple slaves (*hierodouloi*) with the title “cat-feeder” (*ailouroboskos*) are known (Engels 1999). According to Diodorus Siculus, cats were given raw fish, or milk with pieces of bread (I.83.2). Feedings were done publicly (I.83.4), and to call the cats for their meal, the caretakers made a clucking sound (I.83.2). Temple cats were

fed lavishly, bathed regularly, anointed with oils, censured with aromatics, and adorned with jewelry (I.84.5–6). In this respect, they were treated very much like the temple's cult images. For male animals, especially fine females were provided as “concubines” and treated with equal splendor (I.84.6). Upon its death, a cat was mummified and awarded a lavish burial (I.83.5, I.84.7–8).

This resulted in vast necropolises of animal burials (Ikram 2005; Bleiberg et al. 2013). Study of the cat mummies from the Bubasteion at Saqqara revealed that the overwhelming majority of cats were domestic, although wild species were also treated in this manner (Ikram 2005; McKnight 2010). Those provided with wooden coffins or stone sarcophagi may have been individual animals singled out and maintained as manifestations of the goddess (Ikram 2005; McKnight 2010).

The vast majority of mummified cats had been desiccated intact (without evisceration) and

wrapped in linen, commonly with an indication of the face provided by shaping of the linen and/or painted details. Some two-thirds of the mummies were immature animals that had died either by strangulation or by a blow to the head (Ikram 2005; McKnight 2010). The temples were evidently breeding cats expressly to be killed in order to create votive mummies, which were sold to worshippers. The devout individual would then offer the mummified cat to the goddess: the souls of the dead animals would serve as intermediaries between human and the divine realm and intercede on behalf of the supplicant (Bleiberg et al. 2013). To this end, literally millions of cats (and comparable numbers of other taxa) were sacrificed, mummified, and interred (Figs. 6 and 7). As fertile as domestic cats are, demand outstripped supply. Examination with X-rays has revealed that the priests also created fake votive mummies with a little or no remains

of an animal (Fig. 7) (Ikram 2005; McKnight 2010).

Because of their utility as controllers of pests, domestic cats from Egypt and elsewhere spread throughout the Roman Empire (Engels 1999; Ottoni et al. 2017). The worship of Egyptian and Egyptian-influenced deities (such as the Greek and Roman goddesses of the hunt, Artemis and Diana, who were identified with Bastet) spread as well. Although the early Christians adopted the motherly cat as a symbol of the Virgin Mary, an artistic motif that continued to appear into the Renaissance (1300–1700 CE), the deep pagan associations of felines might have resulted in their later identification as animals of witchcraft and consequent episodes of persecution of the cat in Europe (Engels 1999; Lawrence 2003).

## Conclusions

The historical reality of the sacred cat – a binary of reverence and sacrifice – is largely at odds with modern imagination and popular culture. Being

identified with gods and other divine forces on account of their appearance, behavior, and “super-human” abilities did not spare cats or other animals from exploitation. On the contrary, religious associations encourage their use not merely as metaphoric imagery and foci of worship but also, first and foremost, as consumables in cult ritual. Culture-specific human perception of specific taxa (either species or higher ranks) and the natural world at large has important implications for conservation efforts, animal welfare, and other human-animal interactions.

## Safari

James A. Oxley

Independent Researcher, Measham, Swadlincote, UK

## Synonyms

Biodiversity; Hunt; Journey; Outfit; Tourism; Wildlife

The term “safari” originates from the East African language Swahili, meaning expedition or outfit for a journey, while utilizing state, communal, and/or private land and currently lacks a specific definition (Roth and Merz 1997; Chardonnet et al. 2002). Historically the term safari was associated with big-game hunting (also known as “safari hunting”) in East Africa that started in the 1800s (Mbaiwa 2008). Safari hunting for tourism purposes, only deemed as tourism since the 1960s, still occurs within many African countries today resulting in various benefits (e.g., employment opportunities, economic benefits) and challenges (e.g., reliance on foreign companies, controversy surrounding its use) (Mbaiwa 2004, 2008).

In the modern day, the term also refers to traveling, most commonly associated with the African savannah, for the purposes of tourism (i.e., viewing and appreciating natural landscape and unique wildlife such as the “Big Five” including lions, giraffe, elephant, rhino, and hippos)

and/or for film/photography and research purposes (Eastman 1995; Roth and Merz 1997). Forms of safari transport vary and may include, but are not limited to, guided vehicles, self-drive vehicles, walking/hiking, hot air ballooning, and horseback. This form of wildlife tourism is well established in many African countries and has been noted to attract large numbers of foreign tourists. Furthermore, safaris have been found to be one of the most popular tourist attractions in Africa as provided by 96% of 145 tour operators surveyed selling trips to Africa from 31 countries, and it has become an economic driver in a range of African countries (Chardonnet et al. 2002; World Tourism Organization 2014). Safaris also take place within other countries, which may be conducted in order for tourists to view specific endangered species, such as the endangered arctic fox (*Vulpes lagopus*) in Sweden (see Larm et al. 2017).

More recently, the term safari has also been incorporated into captive zoological collections, such as drive-through wildlife parks (e.g., Woburn Safari Park, UK), while the term has also been used within zoos to highlight resembling themes and species of the African savannah and/or for events such as “Safari in the City” held by ZSL London Zoo in 2017 which raised over £375,000 in order to help tackle poaching and illegal wildlife trade (ZSL London Zoo 2017). The safari theme has also been incorporated in other commercial aspects and has influenced areas ranging from films to fashion (e.g., safari chic). More research is required to help to further understand the definition and perceptions of the term and its use in relation commercial settings and within popular culture.

In summary, despite the popularity of safaris, both in terms of tourism and use of the term in popular culture, more evidence-based research is needed on safari hunting, tourism, and how it affects wildlife and the environment in which it occurs. This would help inform safari stakeholders about future planning, monitoring, and governance of such activities especially in areas which hold small groups of endangered species. Further research could also investigate alternative

avenues (e.g., virtual tourism) that may ensure endangered species are protected while ensuring minimal environmental disturbance.

## Introduction

Animal communication occurs when a sender exchanges information, through a codified signal, with a receiver to the benefit of both. In anurans, communication is notorious during courtship and male-male agonistic interactions. Usually, males advertise their presence and readiness to mate while keeping rival males at bay, whereas females scrutinize chants in order to assess males' qualities and choose preferable partners (see Vallejos et al. 2017 for an exception). Thus, in most species, signals are primarily produced by males, placing them as senders and receivers, while females act mainly as receivers (Gerhardt and Huber 2002). In this section, we synthesize studies on anuran senders and receivers, what sort of information they exchange, what are the signals, and how they are produced and transmitted in anuran interactions. Moreover, we examine potential communication modalities

based on observed sensory cues perception by conspecifics.

Because anurans communicate primarily via acoustic signals, other sensory modalities seem to have been neglected for a long time and have only recently received more attention (Starnberger et al. 2014a, b; Woodley 2015). Recent studies have reported alternative modalities such as chemical and tactile communication. Additionally, for most vertebrate groups, communication has been shown to occur through complex signaling, composed of multi-sensory modalities. These signals are frequently referred to as “multimodal.” Possible causes and functions of multimodal signaling in anurans are based on behavioral field observations and experimental tests.

## Acoustic Communication

Calling activity is the primary communication mechanism for anuran amphibians (Gerhardt and Huber 2002). Each anuran species can have distinct vocalization patterns, and individual frogs produce a variety of calls, for which several distinct categories are recognized (Toledo et al. 2015). Several authors have proposed classifications and categories for the calls emitted by anurans (e.g., Duellman and Trueb 1994; Wells 2007). Recently, Toledo et al. (2015) standardized the anuran call classification, with 13 distinct call types, which can be divided into 3 categories according to social context: (1) reproductive, (2) aggressive, and (3) defensive.

Reproductive calls are the most commonly heard and with the highest value for systematics due to its function as an important premating isolation mechanism. Advertisement calls are long-range signals emitted usually by males during breeding season to attract conspecific females for reproduction. A single male's call usually reveals its species, sex, reproductive state, and location. This call can also attract males at a long distance to join the chorus and might be used to establish territorial limits for conspecifics (Toledo et al. 2015; Köhler et al. 2017). More than five types of

reproductive calls have been proposed for anurans: courtship, amplexant, release, post-oviposition male release, and rain calls (see Toledo et al. 2015 for further definitions).

Aggressive calls are emitted by male frogs to defend their calling sites against conspecific competitors. Territorial call, the most common of this category, is emitted by males defending specific resources inside a territory like the calling, egg laying, retreat, or feeding sites. Consequently, this call acts by setting boundaries between males in a reproductive chorus. There are another three types of aggressive calls described for anuran species: encounter, fighting, and displacement (see Toledo et al. 2015 for further definitions). Besides the aforementioned categories, three sub-categories (alarm, distress, and warning calls) of defensive calls are interpreted as adaptations to prevent predation (see Toledo et al. 2015 for further definitions).

## Structures of Bioacoustic Signals

Sound is a pattern of transmitted energy through pressure waves. Wave components can be depicted in sound graphs, illustrating changes in amplitude over time (oscillogram) or transformed into frequency domains through a fast Fourier transformation, which decomposes the complex waveform into sine waves for analysis, producing spectrograms and power spectra (Fig. 1). Many sounds concentrate energy in several separate, evenly spaced frequency bands, called harmonics, which are multiples of the lowest harmonic (i.e., first or fundamental; see Fig. 1). The dominant frequency is the one that contains the greatest amount of energy. This can be either the fundamental frequency or one of its harmonics (Ryan 2001; Vitt and Caldwell 2013; Köhler et al. 2017).

Bioacoustic signals are divided into units (call) and subunits (notes and pulses). The term pulse applies to short signals, with a single unbroken wave train delimited in time by significant amplitude reduction. Notes are usually groups of pulses and the main subunit of a call, with short intervals, relative to total call length, of 100% amplitude modulation (i.e., silence) between them. Calls are the primary structure of an anuran

**Salientia Communication, Fig. 1** Oscillogram (a), spectrogram (b), and power spectrum (c) of a single hypothetical call composed of three notes with three pulses

each. Note the first three harmonics indicated in b and c. The fundamental frequency (lowest band in b) corresponds to the dominant frequency (highest peak in c)

acoustic signal and are separated from other calls by periods of silence (typically much longer than the call). Calls may be composed of one or several notes of the same type (simple call) or different types (complex call) (Köhler et al. 2017). The waveform shape of a call, note, or pulse is called

envelope. A period is the duration of a call structure, unit or subunit, plus the interval between consecutive structures. Repetition rates are the number of such call structures emitted per period of time, usually per one second or minute (Ryan 2001; Köhler et al. 2017).

## Mechanisms of Sound Production and Reception

The basic mechanism of sound production in most anurans is activated while exhaling. A positive pressure, created by the contraction of muscles in the buccal cavity, pumps air into the lungs. Then, contraction of trunk muscles forces the air from the lungs into the buccal cavity, through the larynx, where it causes the vocal cords to vibrate and produce sounds. These sounds are further modified by muscles of the larynx and associated cartilages, between the lungs and the buccal cavity. Then, such morphological structures are more developed in males. Exceptions to this sound production process can be seen in *Bombina* (during inspiration) and in *Discoglossus* (during both inspiration and expiration) (Wells 2007).

The anuran laryngeal apparatus lies between the lungs and the buccal cavity and therefore is involved in both respiration and sound production. In most anurans, the larynx is composed of a pair of arytenoid cartilages, which houses the vocal cords. These moveable cartilages are supported by the cricoid cartilage, which attaches the larynx to the hyoid apparatus and serves as a point of attachment for various muscles. The vocal cords can only be stimulated when the arytenoid cartilages are apart, allowing air flow through the larynx. In the family Pipidae, however, males lack vocal cords and use a modified laryngeal skeleton to produce sound. Calls consist of sharp clicking sounds produced when the arytenoid cartilages are suddenly pulled apart. Sounds are amplified by an enormous boxlike cricoid cartilage. Hence, sound production in pipids requires contraction of the laryngeal muscles, but does not involve contraction of the trunk muscles or the production of vibrations in an air stream (Duellman and Trueb 1994; Wells 2007).

In males of many frog species, vocal sacs are connected to the buccal cavity, typically via slit-like openings, and are inflated during vocalization. The vocal sac is not an acoustic cavity resonator as it was previously suggested, although it may serve to direct the call toward the receiver or as a reservoir of mechanical energy during

calling. Morphology varies from a median single subgular sac to bilobate and paired subgular sacs or paired lateral sacs. Anuran vocal sacs can be slightly or highly distensible and are defined as either internal or external vocal sacs. Their form and color might also have a role in visual signaling (Wells 2007; Köhler et al. 2017).

Anurans have a large tympanic membrane of thin, nonglandular skin, which receives airborne sound waves and transfers sound pressure-induced vibrations to the columella in the middle ear. These vibrations disturb the fluids in the inner ear through the oval window between the columella and the inner ear. Within the anuran inner ear, two sensory organs are largely responsible for the perception of airborne sounds: the amphibian papilla, sensitive to low and mid-frequencies (typically 50 Hz to 1 kHz), and the basilar papilla, sensitive to higher frequencies (above 1 kHz). Some anurans species, however, lack tympanic membranes, columella, or even middle ear cavities and might communicate effectively with airborne sounds throughout the *opercularis* system, which detects vibrations from the substrate. However, recently, two anuran species (*Brachycephalus ephippium* and *B. pitanga*) lacking tympanic membrane, extrastapes, stapes, and middle ear cavity – hence considered “earless” – are deaf to high-frequency signals, suggesting that these species are unable to perceive their own produced calls (Goutte et al. 2017).

## Morphological and Environmental Effects on Acoustic Signals

Noise is any unwanted sound that interferes with the detection of a signal and the information transmission, being a combination of non-biological or environmental noise (e.g., wind and turbulence) and biological noise (sounds from other animals) (Forrest 1994).

Many individuals of a different number of species using the same breeding sites could generate noise and become a potential problem (Stebbins and Cohen 1995). Heterospecific acoustic interference have diverged due to temporal characteristics of their calls (calling rate, call duration, call complexity, or the number of notes), spatial

separation at breeding sites, and spawning and in other ways. Vocal divergence helps to ensure species recognition and reduces the chances of mismatings between closely related species and wasted reproductive effort serving as an efficient premating isolating mechanism (Forrest 1994; Ryan 2001; Gerhardt and Huber 2002).

Naturally, the sound's pressure, intensity, and fidelity decrease the longer the distance it travels. The call can be attenuated and degraded, and the surrounding environment might impose a strong constraint on it by means of sound refraction, reflection, and absorption along the transmission path. Sound scattering and reflection also play a role in call degradation, defined as the decreasing of call integrity by losing definition in temporal traits and amplitude patterns. So, long-range communication must be efficient in order to overcome these issues. For effective mate attraction, the call should not only have sufficient intensity when it reaches the receiver to be detected, but it must also be discernible as a conspecific call (Ryan 1988; Forrest 1994; Wells 2007).

Habitat can differentially affect aspects of the calls. For instance, reverberations are almost completely absent in open habitats. On the other hand, signals in open habitats are prone to degeneration from different sorts of temporal interferences, like the wind (Ryan 1988).

The speed of a sound depends on air density and temperature. Sound travels faster in warmer air; thus temperature can influence spectral properties of calls. Temperature can be especially important when it affects properties of calls used by females to discriminate among sympatric species (Ryan 1988). Furthermore, anurans are ectotherms, and temperature influences those attributes of acoustic signals that are controlled by neuromuscular system (e.g., call, note, and pulse rates and durations) (Gerhardt and Huber 2002; Wells 2007; Köhler et al. 2017). Usually, researchers evaluate the strength of the association between environmental temperature at the time of recording and acoustic features by means of correlation tests or linear regression (Köhler et al. 2017).

The body size is usually strongly correlated with spectral traits, suggesting that fundamental

and dominant frequencies are under morphological constraints. Since larger vocal cords are able to vibrate at lower frequencies and larger frogs usually produce calls at lower frequencies, vocal cord mass and length seems to be directly proportional to the frog's size. However, temporal traits have only rarely been suggested to be influenced by body size (see Bee and Gerhardt 2001). Besides the body size, call frequency can also be actively modified by changing the tension of the vocal cords associated with the contraction or relaxation of various muscles associated to the larynx (Gerhardt and Huber 2002).

### Social Interactions

Choruses are aggregations of acoustically signaling animals, formed by individuals of different species in areas where physical resources (within or along the margins of standing water in anurans) required by females to lay their eggs are present. Such behavior can reduce individual risks of predation making harder to find signaling individuals or by increasing the chances of predators being detected by some individual who then alerts the rest of the group. Chorusing increases the range of female's attraction since a group of signalers can be heard louder than single individuals at great distances. On the other hand, these aggregations intensify the competition among males to attract mates, to acquire and defend resources needed by female, or both (Gerhardt and Huber 2002).

Satellite behavior is a tactic in which males do not call while situated near a calling male, parasitizing the calling efforts of other males. This behavior usually depends on the individual's age, size, energy reserves, physical condition, signaling ability, and density of calling males. This tactic may be the only chance to mate for small, young, or weak individuals in species in which larger, established males hold territories and attack other males within or near their territories. Satellite males can intercept females that are attracted to the calling male, wait for the calling male to vacate its territory or calling site, or both (Gerhardt and Huber 2002; Wells 2007).

To avoid interference of overlapping conspecific calls, males commonly alternate their

calls when close to one another, a behavior essential to preserve energy when high calling rates are emitted, particularly in those species that have prolonged breeding period and in which males are territorial.

### Honest and Dishonest Signals

Sexual selection encompasses the array of behavioral tactics used by individuals to acquire mates. Females select males as mates and represent a limiting resource and object of competition among males. Thus, males are subject to more intense sexual selection than females, and traits that enhance the ability of males to locate, attract, capture, or retain possession of females will be favored by sexual selection, as will traits that reduce the amount of time between successive matings (Wells 2007).

Honest signs transmit reliable information from sender to receiver. There is a general assumption of sexual selection that signals given by males to attract females tend to be energetically expensive to produce. Females often are attracted to males that emit long, loud, or high-rate signals, traits that are positively correlated with levels of energy expenditure (Ryan 2001). The energy cost usually keeps the signal traits honest and then reliable to receivers while assessing senders' information (Searcy and Nowicki 2005).

Besides the signal costs, constraints can influence in keeping signals honest. Given the physical body-size constraint of frequency in anuran calls, females and male competitors can interpret frequency traits as an honest signal portraying body size of the sender and, thus, its strength and quality. The fundamental frequency of calls is partially determined by the shape and size of laryngeal apparatus, which in turn is constrained by the body size (Bee et al. 2000; Wells 2007; Köhler et al. 2017). Thus, females and males rely on spectral properties of acoustic signals to assess male's quality and opponent's size during courtship and aggressive encounters, respectively (Bee et al. 2000; Köhler et al. 2017).

There are a few reported cases of dishonest signaling in anurans. In some species, males can alter call properties in order to emit a dishonest signal and be perceived as being bigger than they

really are. For instance, in *Lithobates clamitans*, small male frogs can alter spectral properties during intraspecific interactions, emitting a dishonest low-frequency call when confronted by larger opponents (Bee et al. 2000).

### Visual Communication

Visual signaling is an alternative or complementary form of communication. This communication can be transmitted over relatively short distance and are often hindered by obstacles in the environment. This means distance (usually individuals need to be less than 50 cm apart) and light are restrictions for the communication process. This behavior may occur in both intra- and inter-specific levels and is associated with reproduction (e.g., for female attraction), aggressive interactions related to territoriality, or predation and might be seen in males only or both males and females.

Species that breed at sites with high ambient noise levels, such as near waterfalls or torrential streams, might favor communication through visual display that either supplement or replace acoustic signals. Background noise might also be produced by other frogs and insects' vocalizations in species that breed in lentic water bodies (e.g., *Boana albomarginata*) and reduces the female's ability to discriminate among conspecific calls. The usual explanation is that the background noise makes vocal communication difficult; thereby close-range communication (visual and acoustical) is favored.

Foot-flagging or arm-waving displays might indicate agonistic contexts. Such displays are usually performed after conspecific males' approach or vocalize close a signaling individual. Once the first visual displays are performed, the outcome of interactions depends on the potential intruder. If the intruder calls, approaches further, or displays visually, the initial display is usually followed by further displays or physical combats. Initial displays or combats usually end when the intruder retreats. However, in some cases, the male starts to emit advertisement calls, and, when close to the female, he starts foot-flagging displays that

presumably increase the female's excitation. The female may respond to the visual signal with the same display or with a different one (Ryan 2001).

Anuran vocal sacs are quite diverse in coloration and shape and have an important role in visual signaling. The change of vocal sac color during the courtship, known for some anuran species, suggests that it could play a role in visual communication. Gular inflation is synchronic with the call emission and may facilitate female localization of individual males in an aggregation. Even in species without distinctly colored vocal sacs, movements of the vocal sac may serve as a visual signal to other males or to females searching for mates (Rosenthal et al. 2004).

Visual communication can also be used in interspecific interactions. Aposematic signals as well as deimatic behavior are important and well-known anti-predator defenses. Deimatic behavior consists of intimidating postures or actions taken when caught by pursuing predators. It is usually associated with aposematic colors or a mimetic behavior. The *unken* reflex is a type of deimatic behavior in which the frog lifts all four legs and arches its back, drawing attention to the bright ventral surface. Such defensive behavior is effective in species with ventral warning coloration (e.g., *Bombina* and *Melanophryniscus*) (Ryan 2001). On the other hand, the eyespot display used by *Physalaemus nattereri* might be a tactic to mimic a bigger animal's body part such as a snake's head (Sazima and Caramaschi 1986).

## Chemical Communication

Chemical signal is the primary source of communication in salamanders (Caudata) and probably in caecilians (Gymnophiona). Historically, chemical communication has been presumed for many anuran species considering their skin permeability and the occurrence of physical contact during the amplexus (Rödel et al. 2003; Willaert et al. 2013). The first evidences suggesting the occurrence of this communication modality in anurans came from experimental studies on chemical perception (e.g., Rabb and Rabb 1963).

Tadpoles of many species are known to be able to detect chemical cues from predators (and injured conspecifics), conspecifics (to avoid intraspecific competition), heterospecifics, and relatives (kin recognition), which may active or passively release chemical compounds (reviewed in Belanger and Corkum 2009). In *Anaxyrus cognatus*, for example, post-metamorphic individuals aggregate possibly guiding each other by using chemosignals (Graves et al. 1993).

Part of the expectation for perception of chemosignals underwater is related to the known complex dual olfactory system of amphibians. Besides the main olfactory epithelium, which is more sensitive to airborne molecules, anurans have a vomeronasal organ (VNO; Belanger and Corkum 2009), which is more sensitive to waterborne molecules (Starnberger et al. 2014b). Apparently, the VNO develops and achieves early significant maturation in tadpoles in order to detect chemical cues in the water (Jungblut et al. 2012). For instance, tadpoles of *Kurixalus eiffingeri*, a Taiwanese rhacophorid tree frog, increase their activity in water conditioned by adult female or male, suggesting chemical perception of conspecifics (Kam and Yang 2002).

Chemical mate recognition and/or attraction based on waterborne substances has also been demonstrated for adults of some species. In the tailed frogs, *Ascaphus truei*, reproductive individuals show a preference for chemical cues from the opposite sex than those from the same sex (Asay et al. 2005). Females of *Ranoidea splendida* are attracted by "splendipherin," a waterborne pheromone produced in males' cephalic glands (parotid and rostral glands; Wabnitz et al. 1999).

Sexually dimorphic skin glands (SDSG; dermal macroglands often called "breeding glands"; e.g., Pearl et al. 2000; Willaert et al. 2013) have been reported for several anuran species (e.g., Brizzi et al. 2003) and recently their intra- and intersexual functions have been observed and/or tested (e.g., Pearl et al. 2000; Starnberger et al. 2013; Brunetti et al. 2014). Taxonomists have described and used presence and shape of conspicuous glands as a taxonomic

feature for many anuran groups (e.g., Vences et al. 2007). Studies on reproductive biology of *Boana punctata* species group (i.e., *B. atlantica* and *B. punctata*), both in field and laboratory, described female contacting her snout to the flanks and gular regions of the male, where lateral and mental glands are located, respectively (Brunetti et al. 2014 and references within). Based on these observations and on the structure of the glands, it is suggested that the mental and lateral glands might produce substances used during courtship communication, as in many plethodontid salamanders (see Wells 2007).

In an experimental study, females of a dwarf African clawed frog, species of the genus *Hymenochirus*, show a positive chemotaxis to water with males or male's homogenized post-axillary breeding glands, whereas males of this species show no response to either water housing males or females, indicating a production of mate-attractant chemosignal (Pearl et al. 2000). On the other hand, the odorous mucus of both sexes functions as a sexual attractant in the terrestrial Australian toadlet *Pseudophryne bibronii* (Byrne and Keogh 2007).

In many anurans (e.g., *Leptodactylus* spp. and *Rana* spp.), males develop, as secondary sexual trait, keratinized spiny nuptial pads on the bases of the first fingers (i.e., thumbs) during the breeding season (reviewed in Brizzi et al. 2003). These nuptial pads usually have associated glands that would presumably produce glue-like substances to enhance the amplexus (Brizzi et al. 2003). Nonetheless, in *Rana temporaria*, these glands produce proteins structurally similar to those found in plethodontid salamanders, called "amplexins," that might stimulate females to lay eggs. Apparently, these proteins could be delivered directly into female's circulatory system through wounds on the female's ventral surface, which result from abrasion between the male's spiny pads and female's skin during amplexus (Willaert et al. 2013).

Although rarer, some studies have reported male-male interactions stimulated by chemosignals (see Woodley 2015). For instance, males of *Leptodactylus fallax* produce a substance

(*Leptodactylus* aggression-stimulating peptide; LASP) in their skin glands induced by intrasexual aggression (King et al. 2005). Males exposed to LASP become more aggressive, displaying behaviors such as jumping and rearing, whereas females had no response to LASP. Males of *Pseudophryne bibronii* avoid substrate marked by other males and react to this, switching from emitting advertisement calls to territorial calls after being exposed to other males' chemosignals (Byrne and Keogh 2007).

Chemicals reported in aforementioned cases are peptides or proteins and then limited to be spread in water or through direct contact (Starnberger et al. 2013; Starnberger et al. 2014a; Willaert et al. 2013). Yet, a few studies also indicate communication via airborne chemical cues (see examples in Woodley 2015). Experiments with the American toad, *Anaxyrus americanus*, show male orientation toward volatile chemical cues obtained from females (Forester and Thompson 1998). Individuals of the poison frog, *Dendrobates auratus*, are attracted to the opposite sex based on olfactory communication (Korbeck and McRobert 2005). More recently, Brunetti et al. (2018) found that the sex-specific volatile components of the Neotropical tree frog, *Boana prasina*, are produced by bacteria of the genus *Pseudomonas* present in the frog's skin. Biochemical and histological analyses of the gular glands of 11 species of 4 hyperoliid genera demonstrated males as capable to produce volatile compounds (Starnberger et al. 2013; reviewed in Starnberger et al. 2014a, b). These glands are located at the gular region of the tree frog males, forming a distinct patch on the inflated vocal sac during calling activity. Moreover, there is a huge compound diversity (65 different types) in species-specific chemical combinations (Starnberger et al. 2013). It has been suggested that these compounds might be actively fanned out and spread into the air by vocal sac pulsations, while males are calling, functioning as a chemosignal in a multimodal communication to species recognition and mate choice (Starnberger et al. 2013, 2014a, b). Species-specific communication via volatile chemosignals is also likely in mantellid

frogs from Madagascar (Poth et al. 2013). Males of many mantellid species have distinct femoral glands (Vences et al. 2007), which produce airborne chemicals capable of increasing individual activity in both sexes (Poth et al. 2013).

## Tactile Communication

Pre-mating touching between male and female has been reported for some species, such as *Aplastodiscus* spp., *Hylodes* spp., *Bokermannohyla ibitiguara*, *Boana atlantica*, *B. punctata*, *B. faber*, and *B. rosenbergi* (Brunetti et al. 2014, de Sá et al. 2016; and references within). For many of these taxa, the amplexus only occurs after female physically contacts the male (see Brunetti et al. 2014; de Sá et al. 2016). Females of *Hylodes japi* can repeatedly touch the posterior part of male's body out of his sight during the courtship behavior, inducing him to emit courtship calls, which suggests the tactile signal as the single stimulus in this case (de Sá et al. 2016). However, for most cases, occurrence of chemical or visual communication during the physical contacts cannot be excluded, making the presence and extension of mechanical stimulus not clear (Brunetti et al. 2014). Moreover, tactile communication studies have failed to fully explain how information can be coded into and assessed from the signals. For instance, in *Boana rosenbergi*, female choice seems to be likely based on differences of male's physical contact. However, how exactly females assess a male's quality through physical contact and what are the preferable signal traits are not known (Kluge 1981).

Tactile stimuli are also frequently observed when tadpoles beg for unfertilized eggs in species with maternal egg provisioning (e.g., Kam and Yang 2002; and references within). Tadpoles of dendrobatid strawberry poison frog, *Oophaga pumilio*, stop swimming and start vibrating their bodies when close to the parents (reviewed in Dugas 2018), while tadpoles of the rhacophorid tree frog *Kurixalus eiffingeri* also nip the skin of mother's cloaca and thighs (Kam and Yang 2002).

## Multimodal Communication

Multimodal communication refers to the cases where the signals are produced and received using two or more sensory modalities. Although anurans have, as well as for most animal taxa, their predominant modality (i.e., acoustic communication), a growing amount of evidences has demonstrated the occurrence of multimodal signals (usually composed of an acoustic signal plus a visual or chemical one; see above). Four information content hypotheses have been proposed for additional components in anuran communication. They may be (1) useless such as in signals produced by-product (epiphenomenon), (2) redundant in relation to that present in the primary modality (i.e., components possess similar information but only one is necessary), (3) complementary as a reinforcement for signal perception by receivers (they make the whole signal more conspicuous to receivers but are still not necessary), or (4) essential as subcomponents of a complex signal, which, if decomposed, would not be perceived by receivers during communication (de Luna et al. 2010).

The different components of the apparent trimodal communication (chemical, visual, and acoustic) of the hyperoliid species might function as redundant stimuli for females (Starnberger et al. 2013). Since these tree frogs usually breed in a multi-species context (i.e., several species communicating and breeding at the same time and space), redundant signals emitted through different channels and sensory systems might facilitate recognition and locating of conspecific males (Starnberger et al. 2014b). In *Engystomops pustulosus*, extra sensory modalities are not necessary for female attraction but may be beneficial for sender while increasing efficacy and conspicuousness of the signal and for the receiver as acting as additional cues to assess male's quality during mate choice (Taylor et al. 2011). Although female tactile stimuli only stimulate males during courtship interactions, a combined bimodal (visual + tactile) signal can be threefold more stimulating than separated ones (de Sá et al. 2016).

Evidences of whether each signal component is important as stimulus come from experimental studies. For example, territorial and aggressive *Allobates femoralis* males only attack other males if a bimodal signal (acoustic + visual) is produced, i.e., there is no reaction in cases with a single modality only (either visual or acoustic; Narins et al. 2003; de Luna et al. 2010). In this species, both sensory modalities seem to act as nonredundant components (de Luna et al. 2010). Initially, the required visual component was attributed to the pulsation of the vocal sac during calling (Narins et al. 2003). However, de Luna et al. (2010) found that body movement can instigate the same aggressive behavior, suggesting that any individual movement can function as an additional component to the acoustic one.

## Conclusion

Anurans primarily communicate intra- and interspecifically through acoustic signals. Males inform their position, readiness, and status to rival males and females. The assessment of male's quality by female is particularly important to species-specific recognition and sexual selection, since females of many species choose mate mainly based on acoustic signals (Gerhardt and Huber 2002; Köhler et al. 2017). Although these signals are the most conspicuous, other communication modalities have received more attention from researchers who have demonstrated them as being more widespread and important within the order than originally thought (Starnberger et al. 2014a, b).

As well as in the acoustic modality, visual and chemical communications occur in both male-male agonistic interaction and male-female mate choice (review in Ryan 2001; Woodley 2015). However, in species with repertoires composed of different signal modalities, regardless of whether the signals are obligatorily synchronized or not, each sensory channel seems to be used in a different phase of the behavioral event. According to field observations, initial phases of the courtship and aggressive interactions usually occur at significantly long inter-individual

distances and, therefore, are similarly dependent on long-range signals such as sounds, whereas final phases of these interactions tend to occur at closer distances, allowing the use of typical close-range signals such as in chemical, visual, and tactile communication (see Pearl et al. 2000; e.g., Starnberger et al. 2013; Brunetti et al. 2014; de Sá et al. 2016).

Even in synchronous multimodal signals, each of them may play a different role and be used for a slightly different purpose in intraspecific communication. In most species with acoustic, visual, chemical, and tactile signals, the former and the latter occur in a long- and close-range communication, while the rest tend to occur at intermediate distances, in short-range interactions (Starnberger et al. 2014a).

Although non-acoustic communications have been historically neglected in the order, the number of reports of chemical, seismic, visual, and tactile signal, during intra- and interspecific interactions, has been growing in the past three decades (Ryan 2001; Starnberger et al. 2014b; Woodley 2015; Köhler et al. 2017). Therefore, we expect to see a significant number of new cases related to all these modalities in the anuran communication literature in the next decades.

## Salientia Life History

Joseph C. Mitchell

Florida Museum of Natural History, University of Florida, Gainesville, FL, USA

The Salientia is a branch of the Amphibia that includes all extinct and living taxa of frogs. The Order Anura encompasses the 6,400+ known and extant species. Frogs occur on all continents except Antarctica and in all of the major biomes of the world. The many life history strategies in these animals evolved in response to the extremely variable niches created by interactions among environments, habitats, and other organisms. About 30% of the world's anurans are

threatened with extinction primarily due to habitat loss and disease (Pechmann et al. 1991).

A life history is a suite of coevolved traits that affect individual survival and lifetime reproductive potential and are studied at the population level. They include age-specific survival, brood or clutch size, size of offspring at birth or hatching, growth rates, interaction of reproductive effort with adult mortality, and variation among these traits in offspring (Vitt and Caldwell 2014). Genetics and environmental conditions such as temperature, rainfall, food availability, predation, and competition influence life history traits. Biologists categorize frog life histories into reproductive modes defined by where the larvae (tadpoles) develop and the primary habitats used by adults. Reproductive modes vary from direct development in the egg out of water resulting in emergence of a miniature adult form (froglet) to eggs deposited in water with embryos hatching into free-swimming tadpoles which remain in water for variable lengths of time then change body form during emergence to the adult form. Species with direct development do not need water for reproduction, whereas those with aquatic tadpoles require water. Species with complex life cycles have gill-breathing, aquatic tadpoles with a body form adapted for swimming, and adults with lungs that have a body form adapted for jumping or leaping on land.

There are 40 recognized reproductive modes for anurans, far more than any other group of animals (Table 1). Except for the handful of species with eggs that develop inside the female, eggs are deposited and fertilized externally. Aquatic eggs are deposited in water often attached to vegetation, in bubble or foam nests on top of the water, or embedded in the backs of aquatic females. Eggs not deposited in water can be on or under the ground, on rocks, in burrows, attached to arboreal sites, in terrestrial foam nests, and carried by adult females or, in some cases, carried by males. Most frog life histories are termed bi-phasic because the aquatic stage (tadpoles) differs dramatically from the terrestrial stage (juveniles and adults). During metamorphosis, tadpoles grow forelimbs (they develop rear legs early in larval development), absorb the tail,

and turn into terrestrial froglets without tails. The wide range of reproductive modes illustrate the many ways frogs accomplish that critical event.

The two ends of the variable life history spectrum for frogs are completely aquatic with all life stages remaining in water and completely terrestrial with some or all of larval development taking place in the egg and within the female (Salthe and Duellman 1973). There are many variations between these two ends. Reproductive modes include egg deposition site (aquatic or terrestrial), larval growth, egg and clutch size, and degree of parental care, if any. These modes affect size at metamorphosis, diet structure, predator escape, individual development, survival, and population growth. These traits are in turn affected by various aspects of behavior, ecology, and physiology, as well as many environmental factors (Wilbur and Collins 1973). The time it takes to progress from egg to sexual maturity is determined by synergistic interactions among all these factors. Individuals that enter the breeding population have survived a highly variable and complex gauntlet.

The most common life history strategy is eggs and gill-breathing, feeding tadpoles in still water, followed by metamorphosis, and lung-breathing juveniles and adults on land. This strategy is the most widespread reproductive mode in anurans. Once deposited in water following mating, frog eggs and resulting tadpoles face many challenges as they develop and grow. The primary challenge is how long water, the hydroperiod, is present. If the pond dries completely before tadpoles complete their development, then mortality is high. Developmental periods of some frogs are short and growth is rapid. This life history trait allows them to be successful in shallow ponds and water-filled depressions with short hydroperiods. Frogs with relatively long larval periods must reproduce in permanent ponds or depressions that do not dry for 1–2+ years, if ever. One benefit to living in ponds and puddles that frequently dry out is that predatory fish cannot establish populations. Larval periods of 15–33 days for Eastern Spadefoot Toads (Fig. 1; *Scaphiopus holbrookii*) in eastern North America and 7–20 days for Couch's Spadefoots (*Scaphiopus couchi*) in southwestern

North America allow these species to be successful in ephemeral pools created by unpredictable rainfall events (Dodd 2013). These frogs can speed up development in response to the rate of pool drying and reduce the lengths of their larval periods. In contrast, the larval period for American Bullfrogs (*Lithobates americanus*; 3–25 months) is much longer and highly variable, which means tadpole survival requires permanent ponds and the ability to survive one and sometimes two winters (Wells 2007).

Complex challenges to individual survival in water begin as soon as eggs are deposited. Those deposited singly or in small groups are more vulnerable to predators than those deposited in aggregations or within thick jelly masses. Egg predators in ponds and pools include a variety of invertebrates such as crayfish, leeches, fish, some turtles, and adult Red-spotted Newts (*Notophthalmus viridescens*). Survival of free-swimming tadpoles is often determined by aquatic predators such as dragonfly naiads, giant water bugs, aquatic beetles and their larvae, fishing spiders, fish, predatory

salamander larvae, and water snakes. Tadpoles hide in vegetation, reduce their activity, and develop colors and patterns on tails in response to the presence of predators. The decorated tails direct predators away from the important part of the tadpole, their bodies. Gray Treefrogs (*Hyla versicolor*) respond to the presence of larval dragonflies by increasing the height and length of their tails and by developing red color near the margins (Relyea 2002). Wood Frog (*Lithobates sylvaticus*) tadpoles increase lengths of forelimbs and legs and lengthen the larval period in response to larval dragonflies (Relyea 2001). Such changes usually occur in ponds that have predatory invertebrates. Such changes do not occur if there are no predators.

Size at metamorphosis is a key life history trait in frogs because it influences adult fecundity. Large metamorphs have a higher probability of survival in terrestrial environments than small metamorphs. The size achieved at metamorphosis depends on interactions among plasticity in growth rates, environmental conditions, food availability, larval density, and abundance and types of predators (Pough et al. 2016).

Reproductive characteristics of frogs vary substantially with elevation and latitude. In general, high elevation anuran populations have shorter breeding seasons, longer larval periods, are larger at all larval stages, larger as adults, reach reproductive maturity at older ages, and produce larger eggs and clutches than populations at low elevations (Morrison and Hero 2003). There are exceptions, however. Temperature is a key factor that influences development rates and growth. In a low-elevation population of Common Toads (*Bufo bufo*) in Europe, age at first reproduction for breeding males and females is 2–3 years, respectively, but increase to 6 and 8 years, respectively, in high-elevation populations (Hemelaar

1988). The timing of male vocalizations and egg deposition in populations of Sauter's Frogs (*Rana sauteri*) in Taiwan shifts from October to December in low elevations to May in high elevations, thus decreasing length of the breeding period and increasing length of the larval period (Su-Ju et al. 2003). Adult females at high elevations are larger and have smaller clutch sizes, but larger eggs and tadpoles, compared to low elevations.

All of these factors affect the number of metamorphs that leave the pond and enter the terrestrial environment. Long-term studies in a South Carolina pond clearly show that the number of newly produced juveniles is significantly impacted by predation, competition among species, and hydroperiod irrespective of the number of breeding females. During one 16-year study, recruitment of juvenile frogs into the population varied from zero to thousands depending on species and years. Female Eastern Narrow-mouthed Toads (*Gastrophryne carolinensis*) bred in abundance in each year, but produced large numbers of juveniles in only one year (Semlitsch et al. 1996). A nearly identical pattern occurred for the Southern Leopard Frog (*Lithobates sphenoccephalus*).

Once juveniles have entered the population and grow to adulthood, their survival is impacted by a host of terrestrial predators (e.g., snakes, raccoons), avian predators (e.g., crows, herons), invertebrates (centipedes, spiders), and environmental factors such as drought and rainfall patterns. In Central America, the calls of male Tungara Frogs (*Physalaemus pustulosus*) attract Fringe-lipped Bats (*Trachops cirrhosis*) that eat them (Ryan 1985). Marine Toads (*Rhinella marina*) also eat calling males of this species (Wells 2007). Semi-aquatic snakes around the world prey on adults that are breeding in water. Herons have been seen catching males of the Southern Toad (*Anaxyrus terrestris*) in Florida while they were calling next to a small pond under a canopy (Mitchell et al. 2017). Adult behavior associated with life histories is an important factor in individual survival and lifetime reproductive success.

Many other frog species have life history strategies that consist of aquatic eggs, free swimming

tadpoles, and terrestrial froglets and adults. Widespread examples include Fire-bellied Toads (*Bombina bombina*) in Central and Eastern Europe (Kuzmin 1999), Marine Toads in Latin America (Savage 2002), Frogs (*Tomopterna* sp.) in sub-Saharan Africa (Channing and Howell 2006), Paradise Toads (*Vandijkophrynus robinsoni*) in southwestern Africa (Du Preez and Carruthers 2009), and Siberian Wood Frogs (*Rana amurensis*) in China, Korea, Mongolia, and Siberia (Kuzmin 1999).

Other reproductive modes that include aquatic eggs and tadpoles also face similar suites of challenges, albeit at smaller scales. Several species in the tropics have taken advantage of water in tree holes and in the axils of bromeliads. Female Coronated Treefrogs (*Anothea spinosa*) in Central America deposit eggs directly into these small bodies of water (Duellman and Trueb 1986). Tadpoles feed on aquatic insects or plant matter and emerge as froglets. The tadpoles of several neotropical frogs, such as Strawberry Poison Dart Frogs (*Dendrobates pumilio*), cannibalize conspecific eggs and increase their own probability of survival (Crump 1983). In some species of *Dendrobates*, females provide food by laying unfertilized eggs along with fertilized eggs. Climbing Frogs in the genus *Anodonthyla* in Madagascar lay eggs in tree holes or axils in vegetation that develop into nonfeeding tadpoles which use their yolks as food to complete development (Glaw and Vences 1994). In this species, males stay with the tadpoles until the larvae are washed out by rain. Some treefrogs in Africa and Central and South America attach their eggs to leaves over water so that once they hatch, the newly formed tadpoles drop into the water where they complete development.

Adults of several species in three Families of frogs in Africa, Asia, and Central and South America construct foam nests (Duellman and Trueb 1986). Secretions from the female's oviduct are churned by rapid movement of her rear legs to create a gray to white foam on the water's surface. Eggs and sperm are distributed throughout the foam as it is being built. In about a week, developing embryos drop into the water where they will grow and complete development. Nests can also

**Salientia Life History, Fig. 2** Sumaco Horned Treefrog from Peru, an example of the life history strategy of eggs deposited on the back of the female where they imbed in her skin and develop directly into froglets. Photo by J.C. Mitchell

be small terrestrial depressions adjacent to water where the eggs hatch when the depression is flooded. Some frogs in Africa and Asia construct foam nests in vegetation over ponds or streams. Early stage tadpoles drop into the water where they will complete larval development. Foam nests protect the eggs and are guarded by males and females in some species.

Eggs of the aquatic Sumaco Horned Treefrog (Fig. 2; *Hemiphractus proboscideus*), a marsupial frog in South America, are deposited on the dorsum of females where they adhere to her skin by gelatinous substances, sink into her skin, and develop directly into froglets (Duellman 2015). All 90+ marsupial frogs in Central and South America carry their eggs attached to their backs or in pouches in which eggs develop and hatch as advanced tadpoles or froglets (Duellman 2015).

Males and females of the fully aquatic Surinam Toad (*Pipa pipa*) from tropical South America undergo a series of somersaults during mating (Duellman and Trueb 1986). When the male and female are on their backs at the top of the loop, the female lays several eggs on the male's belly where he fertilizes them and roll the eggs onto the female's spongy back where they adhere. Her skin envelops each egg separately creating a brooding pouch. All development occurs in the pouch, and at metamorphosis 3–4 months later, the toadlets hatch by breaking through the female's skin.

Some species avoid the aquatic gauntlet altogether. Frogs in the speciose genus *Eleutherodactylus* (Rain Frogs) in Central and South America lay terrestrial eggs in moist soil or in leaves on the ground or vegetation over water that develop directly into froglets (Wells 2007). Female Mozambique Rain Frogs (*Breviceps mossambicus*) in east Africa lay about 20 eggs in jelly in a small chamber she makes under a rock (Channing and Howell 2006). Tadpoles do not swim or feed in the soft jelly; metamorphosis into froglets occurs about 6–8 weeks later.

The role of the male is not always to fertilize eggs. Midwife Toads (*Alytes obstetricans*) in Europe mate on land and males wrap strings of 20–50 fertilized eggs around their hind legs (Spellerberg 2002). Fifteen to 45 days later, they carry the eggs to a pool or pond where the eggs hatch into free-swimming tadpoles. Males of many South American poison dart frogs stand guard near their eggs and tadpoles. Some, such as Common Rocket Frogs (*Colostethus panamensis*) in Central America, carry tadpoles to water on their backs (Wells 2007). Others simply sit on the eggs to guard them (e.g., Green Poison Frog [*Dendrobates auratus*]).

A few frogs have internal fertilization and the eggs develop into late-stage tadpoles or froglets inside the female's body cavity. Critically endangered Kihansi Spray Toads (*Nectophrynoides asperginis*) in Tanzania accomplish internal fertilization by males depositing sperm into females by pressing his cloaca tightly to hers (Channing and Howell 2006). There is no intromittent organ in this or any other species of frogs. Fertilization and complete development occur in the oviducts; toadlets emerge through the cloaca at metamorphosis. The Golden Coqui (*Eleutherodactylus jasperii*), now extinct in Puerto Rico, combined internal fertilization with egg retention in the oviducts and subsequent birth of froglets (Wells 2007). Tadpoles of two species of *Nimbaphrynoides* (Liberia Nimba Toad [*N. liberiensis*] and Western Nimba Toad [*N. occidentalis*]) in West Africa complete development in the female's oviducts while they subsist on their yolk (Wells 2007). A new species of

Fanged Frog (*Limnonectes larvaepartus*) on the island of Sulawesi has internal fertilization, complete development of eggs within the oviducts, and live birth of late-stage tadpoles and occasionally froglets (Iskandar et al. 2014). Tadpoles initially feed on their yolk reserves, but then feed on secretions (“uterine milk”) from glands inside the oviduct. The froglets emerge following internal metamorphosis.

Female Gastric Brooding Frogs (*Rheobatrachus silus* and *R. vitessinus*) in rainforests of eastern Australia picked up the eggs after fertilization and swallowed them (Tyler 1994). All of the tadpoles developed into froglets in their stomachs and emerged as toadlets through their mouths. Birth was rapid with females disgorging all the froglets at the same time, called propulsive vomiting, in water. The many unanswered questions about how they accomplished this extreme behavior will have to remain so because both species are now extinct.

Questions about and scientific studies on frog life histories began in the 1800s and expanded in the 1900s. Since then, ecologists have discovered most of the life histories that deviate from the biphasic tadpole-in-water and adult-on-land strategy and most of these species occur in the New World tropics. The extraordinary variation in frog biology means that the 40 life histories we know of today will likely not be the whole story. New species and strategies continue to be discovered in the twenty-first century. Unfortunately, we may miss some of them because frogs are going extinct at a frightening rate. Loss of the Gastric Brooding Frogs is only the start. Additional information on frog life histories can be found in the references cited here and in a recent review by Crump (2015).

## Synonyms

Anuran gaits; Anuran locomotion; Frog locomotion; Salientia gaits; Toad locomotion

## Definition

Movement used by anurans (i.e., frogs and toads) to traverse their environment.

The Salientia, or the anurans, is an order within Amphibia. This order includes all extinct and living species of frogs and toads (Mitchell 2017). Frogs are inhabitants of all major ecosystems in the world where water is present, except in areas where there are less-than-ideal temperature conditions (i.e., Antarctica). Anurans possess a diverse set of locomotor modes that allow them to function in varying environments, such as swimming, jumping, hopping, walking, and in some instances burrowing. Current and extinct species of Salientia also provide researchers crucial insight regarding the evolution of modern-day amphibians.

## Metamorphosis

A proper analysis of anuran locomotion cannot be conducted without analyzing basic development, anatomy, and life cycle (Fig. 1). Most anurans follow a common life cycle that includes a tadpole stage followed by a metamorphosis that transforms them into an adult form. Some anurans can completely bypass the tadpole stage and develop into their adult form in a process called “direct development” (Elinson 2001). Despite this unusual transition within some species, the great majority of anurans undergo a standard metamorphosis in which they transform from their freshwater form (tadpole) into a terrestrial form (frog or toad) (Herner and Frieden 1960).

The anatomy of the tadpole does not resemble the typical adult or other larval vertebrates. Anatomically, tadpoles are characterized by a bulbous head attached to a relatively small body and tail (Elinson 2001). The tadpole's sole locomotor mode is swimming since it lacks both fins and functional limbs. Propulsion during locomotion is provided by the tail (Elinson 2001). All larvae possess gills for respiration, which serve as their main modality of gathering oxygen from their environment. Anurans can remain in their larval stage for varying periods of time dependent on

**Salientia Locomotion,**  
**Fig. 1** Anuran

metamorphosis involves a locomotor transition from fully aquatic undulatory swimming tadpoles (**a** and **b**) to limb-powered quadrupedal walking, hopping, and swimming (**c–e**)

their specific species. Some species remain in their larval stage for only a few days while some others can remain in their larval stage for anywhere from 3–5 years (Dodd 2013). Despite this varying time frame, all tadpoles eventually mature until the point where they undergo metamorphosis.

The tadpole-to-adult metamorphosis involves a complex set of morphological and physiological changes that radically alter the body plan of the larvae. Once the metamorphosis is complete, they transform into a form they will carry through adulthood. In the adult stage, all frogs are quadrupeds. They all share a common body structure consisting of a short head, bulging eyes, little or no neck, a short compact body, and paired forelimbs and hindlimbs. Another important distinct feature is that frogs, unlike their tadpole stage, lack a tail (Dodd 2013). Despite the lack of a tail, adult anurans still possess the ability to swim.

### Major Locomotor Modes

Anura is a specious order and the methods of their locomotion mirror this diversity. The main methods of anuran locomotion are jumping,

hopping, walking, swimming, and in some cases burrowing. The percentage of utilization of each mode might vary interspecies, but all species still use these modes to some degree.

The most common method of locomotion among terrestrial anurans is jumping. Jumping is defined as a catapult mechanism. This is when muscle contraction is used to store energy in elastic structures such as tendons/ligaments (the loading stage). The stored energy in these structures then recoils releasing a large amount of energy in a short amount of time (the recoil stage). Jumping involves a synchronous extension of the hindlimbs. This extension starts proximally and moves more distally, starting at the hip joint followed by the knee and then by the ankle. Most of the power is generated in the flexion–extension axis. There is very minimal adduction/abduction that occurs during jumping. Strain energy is primarily stored in the large Achilles tendon. Hopping involves this same mechanism of movement but has some slight differences. The difference is the distance covered during one leap. A jump is a leap greater than ten snout–vent lengths. A hop is a leap less than ten snout–vent lengths. Jumping anurans tend to have long hindlimbs, while hopping anurans have shorter hindlimbs. Hopping is characteristic of toads

while jumping is characteristic of frogs (Simons 2008).

Additional terrestrial modes of locomotion exhibited by anurans are walking and running. This involves the asynchronous motion of the hindlimbs to produce force. Walking is defined as a gait in which each foot is in the stance phase for at least 50% of the stride. Anuran walking consists of a sequence in which each hindlimb footfall is followed by an ipsilateral forelimb footfall (i.e., right hindlimb, right forelimb, left hindlimb, and left forelimb) (Fig. 2). The movement during walking is modeled by an inverse pendulum because the leg during the stance phase is rigid and the body rotates around it. The body's center of mass is highest at mid-stance. Then the body arcs downward and forward over the stance foot. This drop in the center of mass is utilized to produce kinetic energy. Running is characterized as a spring-like gait. During the beginning of stance phase the leg is compressed and stores potential energy within the tendons and muscles. At mid-stance, the center of mass is at its lowest. After mid-stance, the tendons and muscles recoil releasing their energy propelling the center of mass up and forward. Increased speed in walking or running is achieved by increasing stride

length and stride frequency. Stride length is modulated by further extending the leg at the end of stance phase. Increasing stride frequency is achieved by decreasing the time in stance phase. There are also increased energy demands on the muscle when moving faster. Speed is related to the type of movement that the salientian exhibits. At lower speeds a walking mechanism is utilized. At intermediate speeds a combination of walking and running gaits is exhibited, this motion is also known as a "trot-like gait." At high speeds only a running gait is seen. Most speeds involve the use of this trot-like gait. This shows that there is no clear transition between walking and running. There is a gradual transition period from the walking gait to running gait. This is not typical in most quadrupeds which have a clear transition speed (Ahn et al. 2004; Granatosky et al. 2018).

Tadpoles possess a unique gait compared to that of adult anurans because they utilize an undulatory motion to swim. This is characterized by a wave-like pattern of movement. The tadpole performs lateral undulations that move from head to tail. This is accomplished by waves of muscle contraction moving caudally. These motions produce linear motion. Some of this thrust is also produced by oscillations at the tadpole's snout. The tadpole also can turn using two distinct methods. They can make very tight turns in response to a mechanical stimulus, such as when the tadpole is at rest and employs this method as a defense mechanism to avoid predators. This motion is characterized by ipsilateral muscle contraction only. They also possess the ability to make wide turns which they naturally do during linear motion. This wide turning motion is characterized by muscle contraction on both sides of the body. Additionally, tadpoles do not have the ability to stop their velocity on their own, rather they rely on the drag from the water to glide to a stop. Tadpole motion is dominated by constant turning after linear motion. They rarely move in a linear path for long periods of time (Hoff and Wassersug 2000).

In adults, the mechanism of swimming is characterized as "kick and glide" motion. This motion involves an extension of the hindlimbs that produces a rapid acceleration. This extension is done

**Salientia Locomotion, Fig. 2** "Hildebrand" plot displaying phase against hindlimb duty factor collected during quadrupedal walking in anurans (n = 8 species)

in a specific pattern starting at the knee, followed by the hip and then ankle. The timing and angle of extension at these different joints vary among species. What remains constant is the qualitative increase in joint angle throughout this kick phase over time. This increase in joint angle over time shows a sinusoidal relationship between the two which is conserved among many species. During the glide phase the hindlimbs are kept in this extended manner as the organism glides losing velocity due to the drag on the body. After this glide, the hindlimbs flex and retract to prepare for the next stroke. The length of this glide phase greatly affects the average swimming velocity of the organism. These kicking leg motions are synchronous which allows for greater thrust and faster swimming when compared to asynchronous motion. This kicking motion can be achieved by either rotational or translational motion of the hind foot. Many species utilize both means of producing foot velocity. The hip, knee, and ankle joints all contribute to translational movement of the foot. Only the hip and ankle contribute to the rotational movement of the foot. Due to the anatomical structure of the knee joint, which points medially, knee extension contributes negatively to the rotational movement of the foot. The hip is the major contributor to translational movement as well as rotational movement of the foot. There is no apparent correlation between speed and the method of producing foot velocity. Both rotational and translational movement are effective methods in producing thrust during swimming. Anurans can increase swimming speed in subsequent strokes by increasing foot velocity, thus increasing thrust. The mechanism of swimming does not differ significantly based on the swimming speed (Nauwelaerts et al. 2001; Richards 2010).

## Bioinspiration

Salientian locomotion may prove to be an excellent model for bioinspired robots. Frogs can adapt to many environments due to their vast locomotive capabilities. Remarkably, the bull frog can jump up to 15x its body length (Reddy et al.

2011). In fact, the jumping mechanism requires so much power that it has been shown that jumping frogs need to deliver a peak power up to 7x higher than the maximum muscle power (Scarfogliero et al. 2007). This powerful jumping mechanism is unique to anurans and has been the basis for several robots designed that simulate frog locomotion. These robots can be used for real-world applications including efficient fast locomotion in unstructured terrains. Robots can be adapted in hopes of environmental monitoring and exploration (Scarfogliero et al. 2007). One proposed robot has quite a simple structure: two degrees of freedom for jump powering and steering, passive forelegs, and feed-forward control (Scarfogliero et al. 2007). This robot has springs in its rear limbs that allow for a powerful jump through a small motor mechanism. In addition, passive, compliant forelegs were developed allowing for soft ground contact which would subsequently allow for preserving stored energy for the next jump. The final robot weighed about 15 g and was expected to run 1.5 m/s, which would correspond to 30 body length per seconds. The most impressive finding of this study was the possibility that a commercial battery could make the robot run for two hours which would in turn cover a distance of several kilometers (Scarfogliero et al. 2007). Innovations such as these have the potential to lead to long-term advances in bioinspired robotics.

Multimodal function has become significant for robots to work in a variety of environments. Robots that can not only jump like frogs but can also swim like frogs have become an active area of research. One research model aims at analyzing frog locomotion in water using cine film recordings and finally implementing those designs in a robotic frog-like system (Pandey et al. 2013). Another research model came up with a model that consisted of a three-dimensional printed robotic body and two legs and feet actuated by dielectric elastomer actuators (Tang et al. 2017). Researching frog locomotion has proven to be useful in creating robots with extraordinary swimming and jumping capabilities. In the future, innovations such as these can prove to be very helpful in a variety of

aspects such as in improving transportation modalities in various terrains.

## Conclusion

Anurans are a diverse order of amphibians that span vast regions near bodies of water. Anurans have a broad variety of locomotor modes that allow them to be successful inhabitants of nearly every ecosystem on earth. These methods of anuran locomotion include jumping, hopping, walking, swimming, and in some cases burrowing. Larval anurans in their tadpole state are quite different than their adult form and are only capable of undulatory swimming. Bioinspired robotics based on the biomechanics of anuran locomotion has proven quite fruitful and the field can benefit greatly from further research into multimodal locomotor abilities of these species.

<sup>1</sup>Setor de Herpetologia, Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

<sup>2</sup>Laboratório de Anfíbios e Répteis, Departamento de Zoologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

## Introduction

Salientia is a superorder of lissamphibians, which includes frogs and toads (order Anura) and the Early Triassic Proanura *Triadobatrachus* and *Czatkobatrachus* (Benton 2015). This is the major extant order of the class Amphibia, encompassing more than 7000 species (Frost 2019) with a high morphological diversity. They are distributed all around the globe, except for the poles and most oceanic islands. Salientia

synapomorphies (characteristics that are shared by the group, derived from a common ancestral) include: lack of a tail in the adult stage; five to nine presacral vertebrae; postsacral vertebrae (posterior to the pelvis) fused into a bony coccyx; and hind limbs elongated, modified for jumping. Other characteristics of Salientia include: fertilization, often external; eggs laid in water or humid places; aquatic larval stage present in most species; males usually with vocal cords, vocal sac, and a voice (Hickman et al. 2014; Kardong 2015). In this section, we synthesize the main knowledge about larval and adult morphologies, and also include changes during metamorphosis, adult sexual dimorphism, and evolution.

## Larval Morphology

Most Salientia species have an aquatic, free-swimming larval stage (tadpole). Tadpoles are typically found in ponds and streams, but some species grow in puddles, roadside ditches, or even in the ground litter. They mainly feed by scraping off the substrate or capturing particles suspended in the water, though there are some predator species. These specialized habits require an entirely different morphology from the adult. Anuran adults have short bodies with long limbs and are tailless, while tadpoles have a tail with fins and are limbless during early stages of development (Fig. 1). Skin, mouthparts, digestive (usually herbivore larvae and predator adult), and respiratory systems (aquatic larvae and air breathing adult) are also dramatically different.

The mouthparts are composed of an oral disk, usually covered with papillae (small dermal projections), several corneous denticles (toothlike projections) arranged in rows, and two strong, highly keratinized, corneous beaks. This arrangement is highly variable according the food habits of the species: tadpoles that scrape stones and other hard substrates usually have more corneous denticles, while predators have reduced oral discs without denticles, but stronger corneous beaks. The position of the mouthparts also reflects food habits: species that feed on deposited particles have anteroventrally oriented mouthparts; species

**Salientia Morphology,**  
**Fig. 1** General  
 morphology of a tadpole

that feed on suspended particles or that are predators have anteriorly oriented mouthparts; species that feed on particles in the water surface have a dorsally oriented funnel-shaped oral disk. Recent studies have also shown a large diversity of internal oral morphology across species.

Besides the variation on mouthparts, the overall morphology varies according to species habits. The tadpoles of pond breeders characteristically have large bodies and deep caudal (tail) fins, which in some species might have a terminal tail extension, like the familiar swordtail fishes (*Xiphophorus*). The mouth is relatively small, located anteriorly, on the underside or upperside of the snout and usually contains weak denticles. These tadpoles swim easily in quiet waters and feed on attached and free-floating vegetation, including algae. In contrast, the stream tadpoles have depressed bodies, long muscular tails, and shallow caudal fins. The mouth is relatively large and usually contains many rows of strong denticles. In highly modified stream tadpoles, the mouth is ventral and modified as an oral sucker, with which the tadpole anchors itself to stones. These tadpoles swim slowly, grazing on the coating of bacteria and algae as they move.

As underwater breathers, tadpoles are lungless and perform branchial respiration. The gills are external in the early stages of development, eventually becoming internalized in branchial chambers or gill cavities due the development of the opercula (gill covering). The water is pumped through the mouth and pharynx to the gill cavity by muscular contractions. After irrigating the gills, the water is expelled through one or two spiracles (small slit- or tube-like openings), depending on the species. Most species have a single spiracle located on the left side of the body. Others possess a single

ventrally positioned spiracle, or two spiracles, one on each side of the body.

In taxonomic studies, tadpole descriptions usually address all of these external features plus others, like eye color and position, nostrils shape and position, vent-tube position (the opening of the cloaca), tail and fin sizes and proportions, body and tail coloration, and presence or absence of neuromasts (mechanical sensors that compose the lateral line). Morphometrically, the following measurements are usually present (Fig. 2): total length (TL), body length (BL), body width (BW), body height (BH), oral disc width (ODW), snout–spiracle distance (SSD), snout–nostril distance (SND), nostril diameter (ND), inter–nostril distance (IND), eye–nostril distance (END), eye diameter (ED), inter–eye distance (IED), spiracle–tail distance (STD), tail length (TL), tail muscle height (TMH), tail muscle width (TMW), and maximum tail height (MTH). In order to enable comparisons between tadpoles with similar development, Gosner (1960) established a table for classifying the development from the one-cell egg (stage 1) to a completely metamorphosed anuran (stage 46).

Tadpoles have a cartilaginous skeleton, divided in a chondrocranium and hyobranchial, axial, and appendicular skeletons. The chondrocranium is a case that houses and protects the brain and main sensory organs, besides supporting the feeding system. The hyobranchial skeleton provides support and directs current water to the gills. The axial skeleton is composed by the vertebral column and is responsible for sustaining tail muscles, playing a fundamental role on under the water mobility. The appendicular skeletons are absent through most of the tadpole's development, appearing only during metamorphosis (Altig and McDiarmid 1999).

**Salientia Morphology, Fig. 2** Schematic drawing of measurements usually presented in tadpole descriptions. (a) lateral view; (b) dorsal view; (c) ventral view. See text for abbreviations

## Metamorphosis

After a variable period of growth, the tadpole undergoes metamorphosis, in which limbs become well developed, and the tail is lost, two of the most obvious morphological changes that take place. Such changes occur gradually throughout tadpole development, the tail loss being one of the last morphological changes. Among the first changes is the appearance of hind limb buds, which grow and develop until completely differentiating into hind limbs with toes, webbing, and tubercles (small, round nodules). Larval mouth parts begin to change; the corneous denticles and papillae, if present, disappear, while the jaws and true teeth develop. A tongue (except in pipids) and associated hyolaryngeal structures develop. The eyes are enlarged and undergo structural modifications; eyelids develop. Later on, the forelimbs emerge through the operculum skin; the tail begins to shrink, being resorbed by the body and the skin thickens following development of dermal glands. The vertebral column and limb bones ossify

(a process that continues during the entire adult life of the anuran), and the adult digestive system differentiates as the long coiled intestine shrinks into a short, thick-walled, folded intestine. The lungs develop, and, for a short period of time, tadpoles have both lungs and gills, before the latter disappear.

How, when and where the changes from larva to adult take place varies greatly across species – a fascinating aspect of studying frogs. The time it takes before metamorphosis depends on the species but also on environmental conditions like temperature and food availability. Most tadpoles complete their development in 2 or 3 months, but there are notable exceptions. Tadpoles of spadefoot toads, genus *Scaphiopus*, develop in temporary rain pools in arid parts of North America, where it is imperative for the tadpoles to complete their development before the pools dry up. Some *Scaphiopus* tadpoles metamorphose about 2 weeks after hatching. In its turn, tadpoles of the neotropical tree frog *Flectonotus pygmaeus* have the intestines filled with yolk and do not feed until the metamorphosis

is complete. They are carried in a female dorsal pouch and metamorphosis is completed in 11–17 days after being released from the pouch and 34–43 days after mating (Duellman et al. 2011). Contrastingly, in the northern part of its range in North America, the tadpoles of the bullfrog *Lithobates catesbeianus* require 3 years to undergo their development.

## Adult Morphology

The name “Salientia” means “leapers.” Not surprisingly, anurans are animals built for jumping, and many of their body features are adapted for this type of locomotion. The short, flattened body provides mid-air stability. Jumping relies on simultaneous movement of hind legs, which are much larger than the front legs, acting as a spring together with the pelvic girdle. The muscles of the hind legs act as a power output generated during a frog’s jump and is enhanced by elastic energy stored in tendons and muscle fibers. The relative size of each toe ensures that all of them will be in contact with the ground during the impulse, increasing friction. Anurans have completely lost their tail and the vertebral column is greatly shortened through reduction in number of vertebrae. The scapular girdle is strongly attached to the column by cartilage ligaments, absorbing the impact on the arms during landing. Bony elements and teeth are reduced in most species, which presumably serves

to reduce the mass of the skull, thereby enhancing jumping performance (Vitt and Caldwell 2013).

Besides jump, anurans might have other modes of locomotion. A few frogs have become almost entirely aquatic and typically have streamlined bodies, large, muscular hind legs, and hind feet with webbing extending to the tips of the toes. Often anurans can burrow in loose soil or sand to escape cold winters, hot summers, or long dry seasons. Such frogs dig with the hind feet, which are often equipped with special tubercles. Their hind legs are relatively short, with the tibio-fibula especially shortened. Tree frogs have adhesive discs on the fingertips, allowing them to adhere to some suspended surface during the jump. Gliding frogs typically have very large toe pads and extensive webbing on both the front and hind feet, and some have skin flaps on the sides of the body and legs. These frogs spread their toes and hold their limbs bent to the sides of the body while gliding, reducing the landing speed and allowing for a longer jump.

## External Morphology

Although most Salientia species are readily recognizable by their external morphology (Fig. 3), there is a great variety of sizes and structural modifications. Many frogs are tiny animals; perhaps one of the smallest adults is the Brazilian *Brachycephalus sulfuratus*, with 8.0 mm or less in

### Salientia Morphology,

**Fig. 3** General morphology of an adult amphibian

total body length, whereas the West African goliath frog, *Conraua goliath*, has a body length of nearly 300 mm. Morphometric measurements are necessary for species delineation, phylogenetic analyses, and even our understanding of evolutionary change in an organism's physical characteristics. In a recent review of morphometric measurements for anurans (Watters et al. 2016), a subset of 16 measurements were recommended as relevant to frogs' descriptions (Fig. 4). These are: head width (HW), snout-vent length (SVL), tibia length (TL), interorbital distance (IOD), head length (HL), eye diameter (ED), internarial distance (IND), eye-nostril distance (EN), foot length (FL), tympanum diameter (TD), thigh length (THL), snout length (SL), hand length (HAL), forearm length (FLL), upper eyelid width (UEW), and Finger IV disk width (Fin4DW). However, frogs continue to grow throughout their life. Thus proportions, rather than actual measurements, are better for comparing samples and species and can

be expressed as ratios of between a specific measurement and the SVL.

The shape of the snout is a reliable and easily discernible taxonomic feature. In dorsal view, the snout can be semicircular, nearly rounded, rounded, subovoid, subelliptical, pointed, truncate, or mucronate; these same shapes are evident in lateral views, although laterally, the snouts of some species are rounded, vertical, obtuse, acute, strongly acute, acuminate or protruding (see Heyer et al. 1990 for more information). Still on the anterior part of the head, two highly subjective characters are present: *canthus rostralis*, the angle of the head from the anterior corner of the eye to the nostrils or to the tip of the snout; and, loreal region, the side of the face between the *canthus rostralis* and the lips. A tympanum and usually a tympanic ring are evident in most species. Commonly, a supratympanic (dermal) fold extends posteriorly from the corner of the eye and passes just above the tympanum and continues onto the flank, sloping downward to a point above the insertion of the arm.

Some characters are found in anuran eyes, such as pupil orientation and presence of pigment on the palpebral membrane. Although the most common orientation is horizontal, some species have vertical pupils. The palpebral membrane is usually transparent (unpigmented) or only slightly pigmented in most species, with rare cases of pigmented reticulation. Also, palpebral and rostral (on the tip of the snout) fleshy appendages might be present in some species, as some of the genus *Proceratophrys* and *Hemiphractus*. In males of many species of frogs, vocal sacs connect to the buccal cavity, typically via slit-like openings, and are inflated during vocalization. Their morphology varies from a median single subgular sac, to bilobate and paired subgular sacs, or to paired lateral sacs.

Structural characters of the hands and feet are of immense taxonomic importance. Alberch and Gale (1985) recognized anuran fingers as homologous to vertebrate digits II–V. The relative lengths of the digits and toes, from shortest to longest, are usually represented in scientific works. Some fighting males have a curved, sharp prepollical spine on each hand, anteriorly to Digit II. This structure

**Salientia Morphology, Fig. 4** Schematic drawing of measurements recommended for anuran descriptions. See text for abbreviations

was thought to be homologous of Digit I, but this idea is no longer accepted. On its ventral surface, both hands and feet might have tubercles, which are classified according to their position, shape, and quantity. Subarticular tubercles are those below the articulations of the phalanges. Supernumerary tubercles are the small ones on the ventral surfaces of the digits, adjacent to the larger subarticular tubercles. Inner metacarpal or metatarsal tubercles are the large tubercles on the ventral surface of the hand or foot, at the base of the shortest finger or toe, respectively. Outer metacarpal or metatarsal tubercles are the small tubercles on the ventral surface of the hand or foot at the base longest finger or toe, respectively. Tubercles might be absent in many species.

Fingers and toes might have an interdigital webbing: a membranous skin that connects them with each other. The presence and extent of webbing on fingers and toes has been emphasized by many authors as a feature for recognition of different species, but it might exhibit considerable intraspecific variation, reducing its reliability for diagnosis. The degree of webbing is expressed in terms of how many segments of the digits (phalanges), hand (distal metacarpal), or foot (distal metatarsal) are free of webbing (see Myers and Duellman 1982; Savage and Heyer 1997 for more explanation).

The skin is the cellular boundary between animal and external environment. It serves as a protective barrier, preventing the invasion of microbes and inhibiting access by potential parasites, resists mechanical invasion and abrasion, and buffers the internal environment from extreme external conditions. The skin also acts in physiological regulation, sensory detection, respiration, and coloration. Several types of epidermal glands are widespread on the head, body, and limbs (mucous and poison glands are always present). The secretions produced by these glands include numerous polypeptides with several activities reported, including antibiotic, antitumor, and insulin-releasing activities. The skin is shed in a cyclic pattern of several days to a few weeks. Using its limbs, the frog emerges from the old skin, which is often consumed.

The color of amphibians is affected by the presence of pigmented cells (chromatophores) in the dermal layer of the skin. The three classes of chromatophores (melanophores, iridophores, and xanthophores) are arranged as a unit and produce the external coloration. Different classes can be combined and arranged to produce a wide range of colors and patterns. In some species, skin color can be quickly altered, in less than a minute, through dispersal or reduction of the eumelanin within the melanophores' processes.

## Internal Morphology

When the first tetrapods colonized the earth, new demands affected their bodily systems. Supporting body weight and moving on the ground, capturing and ingesting food, breathing and mating were challenges to overcome. The musculoskeletal system was, perhaps, the most affected in this transition. The Salientia, of course, inherited morphological solutions for these challenges and adapted them for their own specialized way of life.

The anuran skeleton is highly specialized. The cranium, much different from other vertebrates, is light, flattened, scarcely ossified and with a small number of bones. Nevertheless, it is resilient enough to withstand the impact of the landing after a jump. The teeth are bicuspid and pedicellate (supported on a pedicel). The vertebral column is very short, with only five to nine presacral vertebrae, without ribs but with overlapping processes that reduce lateral movement. The post-sacral vertebrae are fused in a long, single bone, the urostyle. Both scapular and pelvic girdles are firmly attached to the vertebral column, a characteristic inherited from the first tetrapods but enhanced by the jumper habit. The posterior limbs are longer than the anterior ones. Both fingers and toes have long and numerous articulated elements (with up to four phalanges), enhancing ability to grab and climb while helping with their ability to jump.

The cranial musculature contains one functional group for jaw movement and another for breathing and swallowing. The jaw muscles are attached to

the dorsal, lateral, and ventral surfaces of the mandible to open and close the mouth. The muscles that function in respiration and swallowing move and support the gills and/or the hyoid and the tongue. The tongue is strong, muscular, retractile, and has a free posterior end. This end is highly glandular and produces a mucus that adheres to the prey, pulling it into the mouth. Thanks to *retractor bulbi* and *levator bulbi* muscles (the latter, a synapomorphy of Lissamphibia) and to the lack of a hard palate, the eyeballs can be pulled into the oral cavity, helping to swallow. The musculature of the vertebral column consists of epaxial (dorsal trunk) muscles and hypaxial (flank or ventral trunk) muscles providing rigidity and strength to the vertebral column and supporting the viscera, respectively. The pectoral girdle is anchored to the trunk vertebrae by axial muscles and absorbs the jump impact. The pelvic girdle has a less extensive muscular system. The limb muscles are divided into a dorsal extensor and a ventral flexor unit, both strong and robust.

Other systems differ less from the basic patterns found in vertebrates. The central nervous system includes the brain and the spinal cord. The brain is divided during development by a flexure into the forebrain and hindbrain, which are further partitioned, structurally and functionally. The forebrain consists of the telencephalon and the diencephalon and the midbrain consists of the mesencephalon and the hindbrain. Twelve pairs of cranial nerves arise from the brain. The spinal cord is a flattened cylinder of nerve cells that extends caudal through the vertebrae. Regarding the sensory system, two characteristics need to be mentioned: the presence of green rods on the eyes and the presence of a second distinct auditory patch, the *papilla amphibiorum* (both are unique to amphibians). The digestive system is simple. The digestive tube includes a large stomach and short intestines, typical of predators. Fat bodies (also called yellow bodies) store fat and are associated with the gonads in all amphibians. In anurans, the fat bodies form numerous finger-like projections which are larger and more pointed in males. These bodies serve as a source of nutrients for the gonads during the breeding period, after which they are in the smallest size. In males of the family Bufonidae, a growth of embryonic

ovarian tissue, called Bidder's organ, is located between the fat bodies and the testicles. It is thought that it can develop in a functional ovary under certain conditions (Pancak-Roessler and Norris 1991).

After metamorphosed, anurans perform cutaneous (through the skin) and pulmonary respiration. The skin is highly vascularized and contributes significantly, but the lungs are always present. These are paired, conical sacs with a pulmonary membrane folded to form internal septa. The lung of anurans is structurally simple when compared to those from other tetrapods, lacking bronchiole, alveolus (like in mammals) and many reptiles) or air capillaries (like in birds). In the absence of ribs and a diaphragm, lung aeration is performed by buccal pumping. Amphibians have double circulation, but the hearth is divided into three chambers: two atriums and one ventricle.

## Sexual Dimorphism

Sexual dimorphism is defined as phenotypic differences between conspecific males and females (Shine 1989). In anurans, it might be observed for many traits, such as coloration, skin texture and skin glands, vocalization, dermal ornamentations, vocal sacs (males), and breeding behavior, body size, and shape (Mesquita et al. 2004). Some differences persist throughout adult life, but others develop in response to gonadotropic hormones and therefore are present only during the active reproductive cycle. Some structures are used in courtship and others for holding the couple in an embrace during mating or oviposition (Duellman and Trueb 1994).

Sexual dimorphism description is very important in taxonomic studies, including body-size measurements, mainly because the female is usually larger than the male. However, interspecific variation in mean body size among closely related species is not clear unless sexual size dimorphism is taken into consideration. Larger body sizes in females might be an advantage for increased fecundity. Nevertheless, competition between males, female choice, parental care, and vocalization are

the main drivers for equal or slightly larger individuals among males in species with aggressive behavior (Kupfer 2007; Han and Fu 2013).

In addition to body size, it is possible to distinguish between sexes externally by the nuptial excrescences (Fig. 5a, b) or hypertrophied forelimbs (Fig. 5c). Nuptial excrescences are associated with male-male combat or with amplexus. Hypertrophied forelimbs can be associated of holding the pair during in an embrace during mating or oviposition. Sometimes, the mature oocytes of adult females can be visually perceptible through the transparent tegument of the venter. Many other anurans exhibit sexual differences in skin texture, with either the male or

female having rough or spiny skin that is not found in the other sex. These differences might function as tactile cues for sex recognition. The same is true for sexual differences in coloration, which is especially common in toads that are diurnally active.

Some frogs have glands of unknown function on various parts of the skin, and in many cases, these are sexually dimorphic or found only in one sex. Ventral glands are known to produce mucus secretions that glue the male to the female during amplexus in some rotund microhylids. In other frogs, these glands can either have the same function or produce pheromones that are transferred to the female during courtship or amplexus.

**Salientia Morphology, Fig. 5** Examples of sexual dimorphic characters present in males (pointed by arrows). (a) and (b) nuptial excrescences. (c) hypertrophied forelimb. (d) vocal sac

Calling is energetically expensive and requires suitable metabolic machinery to supply the muscles with large amounts of energy and oxygen. Vocalizations are usually emitted by males during the breeding season and the machinery necessary for its functions are: strong trunk muscles and large laryngeal apparatus in males than those of females; and vocal slits and sacs developed in males for most species (Fig. 5d).

When external sexual characters are absent or not visible, it is possible to determine sex and reproductive conditions through direct observation of the gonads. The bilaterally paired ovaries are ventromedial to the kidneys and suspended from the body wall by a pair of mesenteries. When enlarged with mature oocytes, the ovaries occupy much of the body cavity and may envelop other abdominal organs. Anurans oviducts are bilaterally paired and lie firmly held by peritoneum along the dorsal surface of the body cavity, extending from an adjacent position (usually ventral) to the lungs, posteriorly to the cloaca, lateral to each ovary. Reproductive males have testis that increase in size and become pigmented in some species during the breeding season. Such structures are attached ventrally to the kidneys by a membrane and usually are spheroid or ovoid small structures.

## Evolution

Whether the Lissamphibia originated from the Lepospondyls or the Temnospondyls remains controversial, though a stronger case for the latter can be found in the literature. Likewise, the relationship between lissamphibian groups is also shrouded in controversy. Recent studies indicate a close relationship between Salientia and salamanders, with caecilians placed as an external group (Benton 2015). Perhaps the discovery of new salientian fossils will shed light on the emergence and evolution of this group.

The oldest known Salientia date from about 247 million years ago, in the lower Triassic: *Triadobatrachus* from Madagascar and *Czatkobatrachus* from Poland. Despite some obvious differences, these fossils closely resemble an

extant anuran, especially regarding the flattened shape of the cranium. The first Salientia had a short tail, unlike the anuran fused postsacral vertebrae (urostyle). They also had a longer body, with up to 14 presacral vertebrae, and the limbs were shorter than that of extant anurans. In general, the overall skeletal morphology of extinct salientian shows an evolutionary path to the jumping habits found in anurans. After a large gap of about 60 million years since the occurrence of these two taxa in the fossil record, the Early Jurassic *Prosalirus* is the oldest known anuran, discovered in Arizona. This species had a vertebral column that resembles the one in modern anurans, though the exact number of presacral vertebrae is unknown. Nevertheless, the jumping habit is clearly already present. During the Jurassic period, anurans had a massive irradiation, and, by the end of this period, fossils attributed to several of the modern families are known. More on the evolution of the amphibians, including the Salientia, can be found in Carroll (2009) and Benton (2015).

## Synonyms

Anuran movement; Anuran navigation; Salientia movement

## Definition

The over 5000 species in the taxonomic superorder Salientia (Latin for “to jump”) represent a group of amphibians in the order Anura – frogs and toads. Anura translates from Latin to “without tail,” meaning that species in this order physically change to a tailless state when transitioning from larval stages to juveniles and adults. Navigation (goal-directed) is movement of an individual

toward a destination, which incorporates information about current location and knowledge of a goal location during movement.

## Introduction

Frogs and toads of the superorder Salientia, also called anurans, are small-bodied, short-distance dispersers who rely on movement and navigation to reach important habitats during their biphasic (i.e., two distinct morphological stages) life cycle. Anurans are sensitive to many stressors because of their limited movement capacity and inherent ties to water for hydration and breeding. Therefore, proximity to aquatic habitats and moist environments are a major driver of juvenile dispersal distances, adult distributions, and migratory strategies. Factors that eliminate or fragment preferred habitats, or limit the ability of individuals to disperse from their natal sites can be problematic to anuran populations. Roads, in particular, can cause both a loss of direct connectivity and a disruption of water flow to breeding/natal sites (Andrews et al. 2008). However, other disturbances risk fragmenting and/or altering microsite conditions, particularly those related to soil moisture. In translocated northern green frogs (*Rana clamitans melanota*) and northern leopard frogs (*Rana pipiens*) Mazerolle and Desrochers (2005) found strong avoidance of disturbed sites as well as disruption in abilities to home back to capture ponds when traversing disturbed areas. Soil moisture has been found to be a key environmental condition that drives habitat preference for ground-dwelling anurans and has been shown to impact movement in bullfrogs (*Lithobates catesbeianus*) and Blanchard's cricket frogs (*Acris blanchardi*) (Youngquist and Boone 2014). Fragmentation of habitats can also have long-term implications for the genetic structure of populations. A study of European tree frogs (*Hyla arborea*) suggested inbreeding effects, as well as evidence of a genetic bottleneck among fragmented breeding ponds in Denmark (Andersen et al. 2004). Connectivity of populations in fragmented habitats is therefore a primary concern for many Salientia species, to maintain gene flow and maximize

opportunities for survival and reproduction among populations.

## Navigation and Orientation Strategies in Salientia

Orientation and navigation mechanisms in Salientia have been a topic of study since the 1960s because of limited movement capacity and high vulnerability to environmental conditions across many species. Adult anurans have been shown to have strong site fidelity (i.e., loyalty) and experiments with translocations of individuals show evidence of navigation ability back to their home site in many anuran species. Oldham (1967) suggested translocated green frogs (*Rana clamitans*) used olfactory cues to navigate back to their breeding site if moved within a reasonable distance; however, when moved at a further distance such that olfactory cues were disrupted, individuals of this species tended to move downhill (presumably toward water) or toward conspecific (i.e., other individuals of the same species) calls. In similar work with leopard frogs Dole (1968) suggested individuals displaced <1 km from their home site were able to successfully navigate a return, but those capabilities diminished at greater distances. He also found that visual impairment did not disrupt homing ability within the 1 km range, providing further support for an alternative cuing ability such as olfaction. Grubb (1970) also found displaced post-reproductive Mexican toads (*Bufo valliceps*) in the fall were capable of orienting back to their initial site of capture, even after a month removed (Grubb 1973). Impairing either the visual or olfactory capabilities of individuals in this species did not impact their homing behavior; however, impairing both senses simultaneously disrupted their ability to orient and navigate back to the capture site. This suggests toads may rely on multiple sensory mechanisms for orienting and navigating in the environment.

Other orientation mechanisms have been suggested, including solar compass orientation in a line perpendicular to the home site shoreline in Fowler's toads (*Bufo fowleri*) (Landreth and Ferguson 1966). This solar compass persisted

into darkness, suggesting either some kind of internal clock mechanism, or a switch to lunar orientation. However, solar compass orientation was disrupted when individuals were displaced at noon, after sunset, under dense cloud cover, or when playing a chorus of conspecific calls away from their home site. Sinsch (1989) later suggested there was redundancy and hierarchical ordering in orientation mechanisms in anuran species, and cueing depended on the degree of displacement and site familiarity. Orientation using a dual-cue system (e.g., olfactory and auditory cues), combined with use of landmarks and piloting (i.e., use of landmarks to drive navigation) in familiar landscapes are the most likely mechanisms for navigation in this group of species.

### Physiological and Behavioral Adaptations for Movement

As anurans transition from aquatic larval stages to terrestrial adults, physiological adaptations for survival shift as well. Once terrestrial, they are vulnerable to a host of predators and require quick movements to escape. They also shift diets and have developed adaptations for rapid capture of prey (primarily insects) in the environment. Adaptations for jumping are therefore paramount for the persistence of these species. Some species (e.g., the striped rocket frog (*Litoria nasuta*)) can leap up to 50 times their body length (James and Wilson 2008). In their terrestrial stage, frogs are physiologically and morphologically designed for jumping. Unlike humans their forearm contains a fused radioulna, and their leg bones contain a fused tibiofibular to provide structural integrity for jumping. Frog ankle bones (tibiale and fibulare) are long, providing leverage (more surface area to push off from) in jumping. The ilium is also long and jointed with the sacrum to provide greater force during leaping, which is also supported by fusion of tail vertebrae into a retracted urostyle. Similar to bone adaptations, a host of muscular adaptations, including enlarged leg muscle mass, have developed to facilitate jumping. Frog leg muscles are astoundingly powerful, capable of exerting more power during a

jump than physiologically possible due to the transfer of energy to an adjacent plantaris tendon, which functions in a catapult capacity to amplify acceleration beyond what is capable by muscle acceleration alone (Astley and Roberts 2011).

Adaptations for navigation in frogs and toads also vary with habitat needs – with different size, shape, and structure of legs and feet found in ground- vs. water- vs. tree-dwelling anuran species. Frogs may have partially or completely webbed feet if the species is primarily an aquatic-dweller, although some arboreal frog species maintain webbed feet for gliding. Tree-dwelling, or arboreal, frog species have mucous-lined padded toes to maintain grip in vertical conditions through adherence to surfaces via surface tension. Many frogs are also capable of walking instead of hopping, which may aid in prey acquisition. Burrowing and other ground-dwelling frogs also often have adaptations called “spades” on their hind feet to aid in digging burrows.

Of utmost importance at all life stages are behavioral mechanisms to aid in the regulation of temperature and water in their environment. Many frogs and toads seek thermal and moisture shelters called refugia underground, under structures (e.g., logs), and/or by shifting to nocturnal periods of activity. All anurans are ectotherms (i.e., rely on external temperatures for function), thus moist skin can help maintain thermoregulation, such as aiding in cooling body temperatures during extreme heat conditions. In temperate zones that experience seasonally freezing conditions, anurans will also undergo a state of torpor (i.e., temperature-induced reduction of activity similar to hibernation in mammals) until external temperatures warm to levels that allow for activity. All of these behavioral and physiological adaptations aid in individual survival and facilitate movement toward preferred refugia areas or away from environmental conditions that would lead to thermal or water stress.

### Dispersal Movements in Salientia

Dispersal in Salientia species primarily (but not exclusively) involves movement of juveniles in a

single direction away from the natal site (where metamorphosis from the aquatic larval phase to terrestrial phase takes place). For anurans breeding in ponds or other standing water bodies dispersal predominantly occurs in juveniles as they transition to the terrestrial life stage. Dispersal typically only occurs once during an individual's life, and generally covers a longer distance than movements of adults during migration, though distance covered is still limited in scope (Semlitsch 2007). Unfortunately, little is known about dispersal mechanisms in juvenile frogs and toads, though there is wide-ranging evidence that individuals are particularly vulnerable while dispersing across unfamiliar terrain (Pittman et al. 2014).

Studies on movement mechanisms in anuran species have become more prevalent in the last decade as the discipline of movement ecology has developed. Individuals at different life stages display different forms of movement for different reasons. Movement may therefore be characterized into “modes,” or phases, based on life stage and behavior in anuran species. Pittman et al. (2014) characterized these phases under a movement ecology framework (see Nathan et al. 2008). In the predeparture phase, newly metamorphosed juveniles initiate movements away from their natal site, often in large numbers of same-aged individuals called cohorts. The predeparture phase can be broken into two distinct substages – preemergence (individuals undergoing recent metamorphosis move to the water's edge and begin to orient themselves for departure) and wait stage (individuals assess timing regarding when conditions are appropriate to depart). Individuals during the predeparture phase may also engage in foray loops where small, temporary exploratory movements are made into surrounding terrestrial habitat with return to the natal site. However, drivers behind decisions to initiate the predeparture phase are still not understood, particularly how individuals assess environmental conditions that suggest greater risk to departure at certain times compared to others (Pittman et al. 2014).

From the predeparture phase, individuals will then move into the initial juvenile movement phase, where it is thought that individuals move

relatively quickly initially from the natal site then slow movement and begin seeking appropriate habitat as they move further away (Pittman et al. 2014). During the movement phase, individuals will decide what distance to and direction to move during each “step” or single movement interval, which may result in a complex movement pattern if turning occurs frequently. Oriented nonrandom movement occurs with greater propensity during the final stages of the initial movement phase as the individual becomes increasingly responsive to habitat in the vicinity – this is termed the directed mode of the initial movement phase (Pittman et al. 2014). This leads to a settlement state within the initial movement phase whereby individuals are searching for specific environmental conditions with greater intentionality (e.g., refugia locations). During settlement dispersing juveniles will begin to establish a small home range where the suite of resource needs can be met in a given area. For anurans, this may include areas centered on moist terrestrial locations (e.g., under logs, rocks etc.), or inundated or flowing water areas for aquatic species. Once settled into a home range, movements tend to shift toward short foraging forays until breeding migration occurs (Pittman et al. 2014). Home range size varies by species and habitat affinity and can range from 1–2 m<sup>2</sup> to 60 m<sup>2</sup> (as shown in green frogs; Martof 1953) or more. Semlitsch (2007) proposed an alternative take on stages of juvenile dispersal for smaller or slow to mature amphibian species, suggesting in the first year recent metamorphs will remain close to natal sites, then as body size and locomotor skills grow, disperse increasingly further distances each subsequent year into adulthood. However, dispersal distances are still generally limited (e.g., <1 km) under this framework.

## Migration in Salientia

Following initial juvenile dispersal from natal sites, many anuran species will undergo seasonal migration as they mature into adult stages. Migratory movements likely evolved as the need to locate and navigate to spatially dispersed resources arose over time. Migration is

differentiated from juvenile dispersal in that navigation and orientation takes place with a known destination in mind. However, the destination is largely constrained by exothermic temperature regulation and moisture/water needs. Migration toward aquatic breeding sites is the most common form of migratory movement in anurans. Breeding anurans show evidence of philopatry (fidelity to breeding sites) and many will return to the same aquatic breeding site for the duration of their life (Semlitsch 2007). Breeding site fidelity has been shown to be preferential in common toads (*Bufo bufo*; Reading et al. 1991) as well as wood frogs (*Rana sylvatica*; Kupfer and Kneitz 2000). Site fidelity may reduce risks of mortality relative to open exploration for better breeding sites. However, many species are also willing to relocate to newer, better sites when made available in close proximity, as shown in Natterjack toad (*Bufo calamita*), gray treefrog (*Hyla versicolor*), chorus frog (*Pseudacris triseriata*), and others (Semlitsch 2007).

Species are known to use a variety of homing and orientation mechanisms (e.g., olfaction, visuo-spatial memory, conspecific attraction) to navigate during migration. Migration movements have been shown to vary among species and between sexes within the same species. Rittenhouse and Semlitsch (2007) showed frogs and toads tend to move further than their salamander relatives, with toads moving at greater distances than terrestrial or tree frog species. In most amphibian species migrating males tend to migrate earlier than females, allowing for ample opportunity for mate choice when females arrive at breeding sites (Douglas 1979). Timing of migration depends on geographic location and thus climate factors that drive local environmental conditions. Often migration movements are closely linked to seasonal rainfall, which provides ephemeral (i.e., temporary) aquatic breeding sites such as pools, ponds, and wet depressions. However, migration movements are also tied to seasonal temperatures as these species need milder temperatures to avoid effects of water or thermal stress during movement. There has even been some evidence of nonbreeding migration between spatially disjunct home ranges, foraging sites, and microsite refugia, or to access important

overwintering locations (Semlitsch 2007; Pittman et al. 2014).

The degree of permeability (or, alternatively, resistance) in the landscape has direct influence on migration of individuals (Sinsch 2014). Some estimates suggest maximum migratory distances in adults of 0.5–15 km from their settlement location. Osawa and Katsuno (2001) found maximum migration distances of 500 m in two species of brown frogs (*Rana japonica* and *R. ornativentris*). If aquatic habitats are clustered, such as a cluster of ponds within a single home range, then frogs and toads may use the entirety of the cluster as breeding centers (Semlitsch 2007). Some evidence points to clustered wetland or pond networks allowing anuran populations to function as metapopulations, or connected subpopulations functioning as a super-population through local extinctions and colonizations among habitat patches (Marsh and Trenham 2001; Heard et al. 2012).

Ensuring that management for dispersal and migration are treated as separate processes can prevent mismanagement as movements associated with dispersal (e.g., departure from the natal site) can be very different than movements associated with migration (e.g., goal-directed seasonal navigation to breeding sites) (Semlitsch 2007). Indeed, the cumulative resources needed to facilitate both dispersal and migration should be a focus of comprehensive management for anuran species. Movements during dispersal and seasonal migration are particularly vulnerable times for individuals (Pittman et al. 2014). Changes in environmental conditions that make habitats and migration corridors less hospitable can have severe fitness consequences for individuals. Fragmentation of habitats may dramatically alter the permeability of landscapes; whereas loss of key habitat features (e.g., aquatic breeding sites) may render an area unusable for the population.

## Conclusion

Much effort is presently focused on conservation behavior approaches to developing creative ways to connect and restore populations of declining amphibian species. Management actions that

restore connectivity to habitats fragmented by roads and that attract adults to restored breeding sites have been promising thus far. Green frogs and leopard frogs have been shown to use substrate-lined PVC tunnels >0.5 m in diameter as an alternative to road crossings (Woltz et al. 2008). Recent research has also shown individuals can be attracted to restored breeding sites using conspecific call playbacks, as found in the endangered green and golden bell frog (*Litoria aurea*) (James et al. 2015). A comprehensive understanding of the ecology of movement, its behavioral mechanisms, as well as the scale at which processes are occurring is critical for conservation of anuran populations (Semlitsch 2007).

terrestrial habitats, and on all continents, with the exception of Antarctica. Their highest diversity is in the New World tropics, with approximately half of known species inhabiting this environment (Vitt and Caldwell 2009).

Members of Salientia undergo dramatic metamorphosis from larva to adult life stages. The fully aquatic larva is physiologically, ecologically, and behaviorally unique from, mostly terrestrial, juveniles and adults. As such, frogs and toads require a variety of mechanisms for sensing both terrestrial and aquatic environments. The most prevalent sensory systems of Salientia include: (1) cutaneous sense organs for mechanoreception, (2) auditory sense organs, (3) well-developed eyes, (4) chemoreception through olfaction and taste, and (5) internal sense organs for proprioception.

## Cutaneous Sense Organs

The skin of toads and frogs contains a number of receptors that inventory environmental cues outside of the animal's body. These receptors include those that register pain, temperature, and pressure. These mechanoreceptors are comprised of free and encapsulated nerve endings in the dermis, with a several spreading into the epidermis (Catton 1958).

The most conspicuous of the cutaneous sense organs is the lateral line system, which is present in the larval stage, and in a few species, through adult stages as well. These mechanoreceptor organs are organized singly or in linear arrangements called “stitches.” Most commonly, these organs are arranged in lines on both sides of the animal's body, behind the head and around the eyes (Elepfandt 1982). In all amphibians, the lateral line organs are superficially located and free standing on the skin so that water directly impinges upon them. The lateral line organs are sensors for water velocity, as the frictional force of the water running alongside the system is proportional to velocity. From each organ, 4–12 cupulae, jelly-like cups surrounding the hair cells, extend up to a millimeter in the water. They are oriented perpendicularly to the organ's axis to allow passing water to deflect the cupulae. Each cupulae contains approximately 40–80 sensory hair cells

## Salientia Sensory Systems

## Introduction

Salientia, the group of amphibians that includes frogs and toads, is a widely diverse clade, with more than 5,450 species documented. Frogs and toads can be found in most freshwater and

(cilia), which respond to deflection from water. The cilia respond to changes in water pressure by bending in only one axis (Tinsley and Kobel 1996). Retention of the lateral line system after metamorphosis is well-documented in all pipids and a few discoglossids, but has also been found in various other families, all of which are characterized by an aquatic lifestyle. Therefore, the retention of the lateral line system throughout ontogeny appears to be related to the ecology of the animal, and not systematics (Tinsley and Kobel 1996).

The response of the lateral line organs to wave stimuli has been studied in aquatic species, *Xenopus*, and through electrophysiological recordings, it was determined that wave amplitude of 0.2  $\mu\text{m}$  can be detected (Elepfandt and Wiedemer 1987). Lateral line organs are innervated by both afferent neurons to locate water flow, as well as inhibitory efferent neurons. Inhibitory efferent neurons are only activated when the animal is swimming, to reduce sensory “noise” that would reduce sensitivity (Russell 1971). The lateral line system is ecologically useful by allowing the animals to detect wave stimuli created by prey and predators (Elepfandt 1984), and orient themselves in their aquatic environment (Elepfandt 1982; Elepfandt 1984).

## Auditory Sense Organs

The ears of frogs and toad are paired sensory structures on each side of the head. The frog’s auditory system has three components: (1) a low-frequency vibration detector (sacculus), (2) a low to mid frequency sound detector (the amphibian papilla), and (3) a high frequency sound detector (the basilar papilla) (Smotherman and Narins 2000). Each ear is comprised of an inner, middle, and outer part. The inner ear is a fluid-filled membranous sac which contains the sensory receptors (neuromasts). The ears of frogs and toads provide two unique functions: (1) the reception of sound waves, or hearing, and (2) balance and the detection of the movement of the body. Neuromasts serve as the receptors for both

of these functions. Similarly to the neuromasts of the lateral line system, the neuromasts record fluid movement along a single axis through deflection of cilia (Smotherman and Narins 2000).

The middle ear contains the bone and muscle that transfers vibrations from the eardrum to the inner ear. The middle ear of frogs and toads has two auditory paths: (1) the tympanum-stapes option for airborne sounds, and (2) the forelimb-opercular option for seismic sounds. The stapes, a single bony rod that extends between the external eardrum and the inner ear, often lies in an air-filled cavity. The limb-opercular option is unique to frogs and salamanders, where sound waves are propagated from the ground through the skeletal system and onto the opercular muscle within the shoulder.

The inner ear consists of two sac-like structures joined by a wide passage. The dorsal structure projects three semicircular canals, which provide sensory information for the animal to properly balance. Each of these canals lies in a different orientation (one lies horizontally, two are vertical, and all three are perpendicular to each other), allowing movement to be documented in three different planes and provide a sense of balance. In frogs and toads, outer ear is minimal, or may be entirely absent (Lombard et al. 1981).

## Photoreception

The structure of the Salientia eye is similar in structure to other vertebrates. The eye consists of a hollow sphere, lined by the retina, the sensory lining of the structure. The sclera, dense connective tissue on the external structure of the eyeball, supports the retina. The transparent part of the outer sheath, which allows light to enter the eye, is the cornea. In postmetamorphic frogs and toads, eyelids and a nictitating membrane provide protection to the cornea. Behind the cornea lies a spherical lens, and the amount of light passing through the lens is regulated by the iris. The opening of the iris, the pupil, is opened or closed by musculature surrounding the iris. The shape of the eye is maintained by the presence of fluid in

the cavity behind and in front of the lens (Vitt and Caldwell 2009).

After light enters the eye, it is focused onto the retina through the lens. The receptor surfaces of the sensory cells face inward, away from the light source. Most members of Salientia have four types of sensory receptors, including red and green rods as well as single and double cones. The cones are responsible for color reception and possess specialized pigments that register a small range of wavelengths. The chemical state of the receptors is changed when light strikes the pigments. The green rods are unique to amphibians, and they are the only vertebrates with double rods. In species with degenerate eyes, these rods become absent. The visual pigment of rods detects all wavelengths of light and therefore only registers the presence or absence of light (Maturana et al. 1960).

The metamorphosis of frogs and toads from aquatic larva to terrestrial adults requires a change in the morphology of the eye. In aquatic conditions, there is no refraction of the light at the cornea; therefore, in tadpoles, all refraction is achieved through the lens alone. During metamorphosis, the lens flattens in to adapt the refraction of the eye for air conditions. In some aquatic species, such as *Xenopus*, the lens remains roughly spherical (Chung et al. 1975).

## Chemoreception

Olfaction is a chemosensory processes performed in paired nasal organs, as well as the vomeronasal organ (Jacobson's organ). Each organ opens to the environment through the external opening of the nostril, and internally into the buccal cavity. In terrestrial frogs, metamorphosis from tadpole to adult requires a shift in chemical detection from water to air. Between the internal and external openings is a large olfactory cavity, with several additional chambers that extend sideways and downward. The surface of these chambers contains mucous cells lined with ciliated epithelium. There are three major patches of ciliated epithelium. The largest patch is found on the roof,

medial wall, and anterior end of the principle cavity. Two small patches occur on the middle of the floor, and another in the vomeronasal organ. Innervation of the principle cavity occurs from the olfactory bulb of the brain, whereas the vomeronasal organ is innervated by a separate olfactory branch (Scalia 1976).

Taste buds are found in all amphibians and are present in two varieties: (1) papillary organs, which are located on the outer surface of the tongue, and (2) nonpapillary organs located throughout the buccal cavity, with the exception of the tongue. Taste buds have been shown to be highly sensitive to salts, acids, and bitter chemicals (Tinsley and Kobel 1996; Vitt and Caldwell 2009).

## Internal Sense Organs

Proprioceptors organs, found in muscles, tendons, ligaments, and joints, are the major internal sensor organs in clade Salientia. These organs provide information on the tension and stress within the musculoskeletal system, allowing the brain to coordinate the movements of the body during locomotion. These organs show structural diversity from simple nerve endings to netlike endings (Vitt and Caldwell 2009).

## Conclusions

Clade Salientia is comprised of a wide variety of frogs and toads, each occupying a range of ecological niches. To navigate life from tadpole to adult, these animals require a number of sophisticated senses to avoid predators, find prey, and maximize their environment, both in the water and on land. While sensory abilities vary by species, frogs and toads largely sense their world through a combination cutaneous sense organs for mechanoreception, a complex sense of hearing, specialized vision, and chemoreception through olfaction and taste, which has led to an extremely successful group of animals around the world (Vitt and Caldwell 2009).

## Introduction

The major goal of comparative cognition is to compare cognition across species. For many years, a species' cognition was rated (compared) on a hierarchy of cognitive-task difficulty with ability to learn abstract concepts typically at the top. Abstract concepts transcend individual features of the stimuli and depend instead on the relationship between stimuli, for example, judging two pictures as being the *same* or *different*. Such judgments can become an abstract concept when they are accurately made to novel stimuli.

*Same/different* abstract-concept learning has a special role in abstract cognitive learning during human development (e.g., learning equivalence and conservation relationships) and provides the basis for more complex strings of equivalent operations involved in novel sentence construction and novel sequences of mathematical operations (e.g., Chen and Mo 2004; Smith et al. 1992). This generalization of equivalence carries forward into adult years, apparently forming the “very keel and backbone of our thinking” as the famous psychologist William James proclaimed 128 years ago (1890/1950, p.459).

Related to human abstract-concept learning is the issue in comparative cognition of which non-human animal species can learn a *same/different* abstract concept. This issue was brought into focus 40 years ago when David Premack (1978) asserted that only humans and language-trained animals (i.e., chimpanzees) had the ability to learn *same/different* concepts. But considerable progress in testing animal cognition and concept learning has been made since Premack’s claim suggesting that a variety of other animal species (baboons, rhesus monkeys, capuchin monkeys, parrots, crows, Clark’s nutcrackers, black-billed magpies, pigeons, and possibly even bumblebees) might have the ability to learn at least a partial *same/different* concept (e.g., Bhatt and Wright 1992; Bovet and Vauclair 2001; Brown and Sayde 2013; Katz and Wright 2006; Katz et al. 2002; Magnotti et al. 2015, 2016; Pepperberg 1987; Wasserman et al. 2001; Wasserman and Young 2010; Wright et al. 1984a, b, 1990, 2003, 2016, 2017).

Nevertheless, obtaining convincing evidence that these animals actually do have the cognitive ability to fully learn a bona fide *same/different* abstract concept can be tricky and likely depends upon: (i) the nature of the relational comparisons being made and (ii) the level of abstractness learned from those relational comparisons. Some tests of relational comparisons used multiple-item visual stimulus arrays where animals (e.g., pigeons) detected differences among items (vs. no item differences) or texture variations from an imbedded item block. Although manipulations of the texture-block size or number of

different items in the array were shown to produce orderly changes, when those arrays were reduced to just two stimuli, accuracy often approached chance performance (e.g., Cook et al. 1997; Young et al. 1997). But bona fide *same/different* abstract-concept learning should also be supported by judgments of two stimuli, the simplest case of relational comparisons. The gold standard for evaluating abstractness and the level of abstractness necessary for claiming bona fide *same/different* abstract-concept learning is full transfer to novel stimuli (i.e., equivalent to the level of training accuracy). In principle, full transfer could be produced by training with a limited (small) set of training stimuli (i.e., small number of exemplar pairs of the *same/different* rule), although this rarely occurs (but see Oden et al. 1988; Smirnova et al. 2015). Some earlier tests of animal *same/different* concept learning used pairs of stimuli, but were too limited in the number of training stimuli (e.g., colored geometric shapes) which resulted in too few exemplars of the rule to obtain full abstract-concept learning (e.g., Blaisdell and Cook 2005; Robinson 1960; Wright et al. 1984; Zentall and Hogan 1974). Humans too require variation in the exemplars to adequately learn rules (e.g., Chen and Mo 2004). Finding partial concept learning tends to be inconclusive and difficult to interpret *vis-à-vis* the cognitive ability to learn the bona fide *same/different* abstract concept.

To overcome issues of (i) interpreting the nature of the relational comparisons being made, and (ii) evaluating abstractness of the relational comparisons, a new approach seemed necessary. Related to the first issue, it seemed necessary to use simple pairs of stimuli for training and testing. Related to the second issue, it seemed necessary to use novel stimuli on all transfer trials and not reuse transfer stimuli to avoid confounding learning and transfer. Also related to the second issue was the level of transfer for establishing abstract *same/different* concept learning. As logic would have it, no transfer would indicate an absence of abstract-concept learning, whereas transfer equivalent to the highest level of training performance would indicate full abstract-concept learning. Having

said this, it follows that interpretation of intermediate levels of transfer (i.e., partial concept learning) would be unclear about whether the animal being tested could or could not learn the bona fide *same/different* abstract concept. Therefore, a manipulation was necessary that would likely affect the degree of transfer and provide a continuum of transfer between little or no transfer to that of full concept learning. The manipulation chosen was the size of the training-stimulus set; small training sets would result in fewer exemplars of the rule and likely less transfer, whereas large training sets would result in more exemplars of the rule and likely more transfer. Accordingly, if partial concept learning was initially obtained, then some larger training set might produce full concept learning. Said otherwise, if a species is truly capable of abstract-concept learning, then there should be some conditions where those individuals can perform as accurately with novel stimuli as they do with the training stimuli. Moreover, there should be a whole function relating the size of the training set to the degree of transfer, which would then provide more powerful comparisons across species than any single level of transfer from an arbitrary selected training set size. To insure that training set sizes would likely reach a sufficiently large set size for any realistic evaluation of full concept learning, training set sizes were successively doubled (logarithmic scale) with training and transfer testing following. This approach required a much larger number of stimuli than earlier approaches using limited numbers of colored geometrical shapes. To make the stimuli as distinctly different as possible, so-called travel-slide pictures (e.g., scenes, objects, animals, buildings, people) were used (see Wright and Katz 2006 for the stimuli used for training in each set size and stimulus pairs used for testing transfer after learning at each set size). This approach of expanding the training set size to generate concept-learning functions was used to obtain full transfer (i.e., abstract-concept learning) and make direct comparisons among capuchin monkeys, rhesus monkeys, pigeons, Clark's nutcrackers, and black-billed magpies.

### **Same/Different Abstract-Concept Learning by Capuchin Monkeys**

The first concept-learning test using these procedures was with three (experimentally naïve) capuchin monkeys (Wright et al. 2003). Trials began with the simultaneous presentation of two pictures, one above the other, plus a white rectangle in the lower right-hand corner (Fig. 1).

If the two pictures were the same, then a touch (choice) to the lower picture was correct; if the pictures were different, then a touch to the white rectangle in the lower right-hand corner was correct. Correct responses were reinforced with a banana pellet. Daily sessions contained 100 trials (50 *same* trials and 50 *different* trials). Monkeys were trained until overall performance was 80% correct or better on three consecutive sessions and were then tested for concept learning. On transfer sessions there were 90 training (baseline) trials and 10 transfer trials (5 *same* trials and 5 *different* trials). Picture stimuli on transfer trials were novel, and six transfer test sessions were conducted consecutively. Correct responses on transfer trials were reinforced similar to correct responses on baseline trials. Transfer trials were intermixed with training trials and trial sequences varied daily. Following transfer testing, the 8-item training set was doubled. Doubling the training set was repeated four times. Transfer testing was conducted following training with 32-, 64-, and 128-item set sizes when performance accuracy was 85% correct (or greater) on a single training session.

As the size of the training set was expanded, there was a dramatic decrease in the number of training trials (from more than 3500 trials to the minimum of 100 trials) necessary to meet the performance criterion relative to the number required with the initial 8-item training set (3533 trials). All three monkeys met the performance criterion in their first 100-trial session with one or both of the two largest set sizes containing 64 and 128 items, respectively. Mean transfer and baseline performances are shown in Fig. 2. Initially (8-item training set) transfer performance with the novel pictures was not significant (51.7% correct) relative to chance performance (50%

**Same/Different Learning, Fig. 1** Examples of *same* and *different* trials. Capuchins were not presented with the sample stimulus alone and instead were presented with both pictures and white rectangle simultaneously. Rhesus touched the sample picture 10 times to get the lower picture and white rectangle. Pigeons, nutcrackers,

and magpies pecked the sample picture 20 times to get the lower picture and white rectangle. A response to the bottom picture was correct on *same* trials and a response to the white rectangle was correct on *different* trials. The other six pictures of the initial 8-item training set are shown at the bottom

**Same/Different Learning, Fig. 2** Mean percent correct performance from three capuchin monkeys on training (baseline) trials (bold broken lines, filled symbols) and novel (transfer) trials (bold lines, unfilled symbols) with successively expanded training sets from 8 to 128 picture stimuli in the *same/different* task. The dotted line at 50% correct is chance performance. Error bars are  $\pm$  one standard error of the mean

correct), a result showing no evidence of any (partial) abstract *same/different* concept learning. As the set size was increased, transfer performance increased to 76.1%, 77.2%, and 86.7% with increases in set size of 32, 64, and 128 stimuli, respectively. Importantly, transfer performance accuracy following training with the 128-stimulus set was equivalent to baseline performance accuracy revealing that these capuchin monkeys had fully learned the *same/different* abstract concept.

### Same/Different Abstract-Concept Learning by Rhesus Monkeys

A group of three rhesus monkeys was trained similar to capuchin monkeys, including the use of the same picture set, simultaneous presentation of two pictures, and the white rectangle, a touch (choice) to the lower picture was correct on *same* trials, a touch to the white rectangle was correct on *different* trials, and daily sessions of 100 trials (50 *same*, 50 *different* trials) (Katz et al.

2002). Surprisingly, only one of the three rhesus monkeys ever learned the task with the initial 8-item training set and that monkey required 200 training sessions to do so; the other two monkeys never showed any learning despite a year (250 sessions) of training. By comparison, all three capuchin monkeys had learned the same initial *same/different* task to the criterion of three sessions of 80% or better in just 34 to 38 training sessions. In order to encourage task learning, this group of rhesus monkeys plus another group of three experimentally naïve rhesus monkeys were required to make 10 touches to the top item prior to being presented with the lower (test) item and the white rectangle (Fig. 1); only then could they make their choice response (*same* response to the lower item, or *different* response to the white rectangle). With this response requirement to the sample stimulus, all monkeys rapidly learned the *same/different* task, at about the same rate (40 training sessions) as did the capuchin monkeys. Importantly, the rhesus group initially trained with 10 responses to the sample stimulus showed novel-stimulus transfer increasing from near chance with the 8-item training set to better than 85% correct with the 128-item set which was equivalent to their respective baseline (training stimuli) performance accuracies (Fig. 3).

Thus, the 10-response group of rhesus monkeys demonstrated full concept learning, similar to that shown for capuchin monkeys. The requirement that rhesus monkeys of the 10-response group respond to the upper picture had a profound effect on their ability to learn the *same/different* task relative to the group not required to respond to the upper picture. This observing response requirement was apparently necessary for the rhesus monkeys, but not capuchin monkeys, to fully learn the abstract concept (see also chapter ► [Primate Cognition](#)). Such fine-tuning of procedures for learning the abstract concept of *same* vs. *different* would be useful later in training and testing avian species (e.g., pigeons, nutcrackers, magpies) for *same/different* abstract-concept learning.

Despite this procedural difference between these monkey species, once the concept was

**Same/Different Learning, Fig. 3** Mean percent correct performance of three rhesus monkeys on training (baseline) trials (bold broken red lines, filled symbols) and novel (transfer) trials (bold red lines, unfilled symbols) with successively expanded training sets from 8 to 128 picture stimuli in the *same/different* task and are compared to capuchin monkeys (thin orange lines, Fig. 2). The dotted line at 50% correct is chance performance. Error bars are  $\pm$  one standard error of the mean

learned by the rhesus monkeys they then could accurately perform the *same/different* task without having to make any observing responses to sample stimuli, a requirement for accurately performing list-memory tasks [see chapter ► [List Memory Effects \(Primacy and Recency\)](#)]. Control tests with other rhesus monkeys included a group where the set size was not expanded, but the numbers of training sessions and transfer-testing sessions were otherwise matched to the experimental group. Transfer by this control group did not improve despite the same amount of training and transfer testing, thereby demonstrating that the manipulation of progressively expanding the training set and exponentially expanding the number of exemplars was the key to learning the *same/different* abstract concept.

### Same/Different Abstract-Concept Learning by Pigeons

Four pigeons were trained and tested with procedures similar to those previously described for rhesus monkeys (Katz and Wright 2006). The successful training and testing of rhesus monkeys that depended upon the monkey touching the sample stimulus 10 times before being presented with the test stimulus and white rectangle prompted the use of a similar response requirement for studies with pigeons. Since pigeons tend to peck stimuli more rapidly than monkeys touch stimuli, the pigeons were trained to peck the sample stimulus 20 times before being presented with the test stimulus and white rectangle (see also chapter ► [Pigeon \(Columbidae\)](#)). Otherwise, the trials and sessions were virtually identical to those used with the rhesus monkeys including, 100 trials (50 *same*, 50 *different*), selected from the same 8-item picture set used to test monkeys. Training continued until performance was 80% or better for three consecutive sessions. Transfer testing was conducted for six consecutive sessions each with the same baseline trials and the same 5 novel *same* and 5 novel *different* transfer trials as used with monkeys. After the first transfer test, the picture set size was progressively doubled to 16, 32, 64, and 128 picture items, like with the monkeys. Because of some uncertainty whether the pigeons would attain full *same/different* concept with 128 items, the training set was also further doubled to 256, 512, and 1024 pictures. Training was conducted with all expanded training sets for a minimum of 3 sessions along with a performance criterion of 85% correct on a single session prior to transfer testing. The transfer stimuli were novel on all transfer tests (see Wright and Katz 2006 for novel testing pairs used for transfer testing after learning with each training set size).

Pigeons initially learned the task in about 30 sessions (range 19–45) similar to rhesus (40) and capuchin monkeys (35). Novel-stimulus transfer increased from 51.3% after learning the task with the initial set of 8 items to 59.6%, 71.7%, 70.8%, 80.4%, 78.5%, and 84.6% for set sizes 32, 64, 128, 256, 512, and 1024, respectively (Fig. 4). For the 256, 512, and 1024 set sizes, the

**Same/Different Learning, Fig. 4** Mean percent correct performance of four pigeons on training (baseline) trials (bold broken green lines, filled symbols) and novel (transfer) trials (bold green lines, unfilled symbols) with successively expanded training sets from 8 to 1024 picture stimuli in the *same/different* task and are compared to rhesus monkeys (thin red lines, Fig. 3) and capuchin monkeys (thin orange lines, Fig. 2). Dotted line at 50% correct is chance performance. Error bars are  $\pm$  one standard error of the mean

levels of transfer were equivalent to their respective baseline levels, thereby producing compelling evidence that pigeons can indeed fully learn the *same/different* abstract concept. Such a conclusion was further supported by two control groups, like with rhesus monkeys, where the numbers of training sessions were matched to the experimental group's training but only the initial 8-item training set was used. One control group was matched in transfer testing to the experimental (expanding training set) group, and another control group was only transfer tested at the very end of the experiment. Neither group showed any evidence of transfer. This is compelling evidence, like that from rhesus monkeys, that pigeons can indeed fully learn the bona fide *same/different* abstract concept and also that this abstract-concept learning depends on expansion of the set of training stimuli.

Notwithstanding the compelling evidence that pigeons can fully learn the *same/different* abstract

concept, the smallest set size for which pigeons attained full concept learning is larger than that for capuchin and rhesus monkeys. This finding means that pigeons need to experience and learn more exemplars of the abstract-concept rule to fully learn the abstract concept than do monkeys. Moreover, the whole set-size transfer function for pigeons is primarily below those for monkeys, showing that the rate of transfer growth occurs more slowly and requires more exemplars of the *same/different* rule than required by monkeys. Such a conclusion highlights the importance of comparing entire training set-size functions, particularly for an important cognitive function like abstract-concept learning that can be compared across a number of different animal species, like Clark's nutcrackers that store thousands of seeds in the autumn, and rely on excellent spatial memory to recover cached seeds to survive winter and spring (Vander Wall and Balda 1977).

### Same/Different Abstract-Concept Learning by Clark's Nutcrackers

Seven wild-caught Clark's nutcrackers were tested for their *same/different* abstract-concept learning with procedures very similar to those used to test pigeons including the same: stimuli, stimulus pairs, sequences of stimulus pairs used in training and transfer testing, display size, and 20 pecks to sample stimuli (Magnotti et al. 2015; Wright et al. 2016). Nutcrackers made their pecks from a perch in front of the stimulus display. Like pigeons and monkeys, a response to the comparison picture was correct when it matched the sample picture. A response to the white rectangle to the right of the comparison picture was correct when the comparison picture did not match the sample picture. Correct choice responses were reinforced with mealworms delivered below the monitor via a rotating wheel.

Like pigeons and monkeys, nutcrackers were trained on 100-trial sessions (50 *same*, 50 *different* trials) until they achieved 80% accuracy (or above) for three consecutive sessions with the same initial 8-item picture set (Magnotti et al. 2015). Following acquisition, abstract-

concept learning was assessed in six consecutive transfer sessions, each session contained 90 baseline (training) trials and 10 novel (5 *same*, 5 *different*) transfer trials. Correct responses on transfer trials were reinforced identically to baseline trials. The training set was then expanded to 16-items, and they were trained until accuracy was equal or greater than 85% correct. The cycle of set-size expansion, training for a minimum of three sessions, obtaining 85% correct or better, and novel-stimulus transfer testing was repeated six times for training sets of 32, 64, 128, 256, 512, and 1024 picture items (see Wright and Katz 2006 for training and testing stimuli).

Nutcrackers maintained a high level of baseline accuracy (85% correct) throughout expansions of the training set size (Fig. 5). Their mean transfer increased from 65% correct with the 8-item training set, to 74% correct with the 8-item training set, to 74% correct with the 32-item training set, 80% correct with the 64-item

**Same/Different Learning, Fig. 5** Mean percent correct performance of seven Clark's nutcrackers on training (baseline) trials (bold broken blue lines, filled symbols) and novel (transfer) trials (bold blue lines, unfilled symbols) with successively expanded training sets from 8 to 1024 picture stimuli in the *same/different* task and are compared to pigeons (thin green lines, Fig. 4), rhesus monkeys (thin red lines, Fig. 3), and capuchin monkeys (thin orange lines, Fig. 2). Dotted line at 50% correct is chance performance. Error bars are  $\pm$  one standard error of the mean

training set, and 86% correct with the 128-item training set. Moreover, this high accuracy level was maintained across larger training set sizes of 256, 512, and 1024 items. The same critical parameter of training set size that was responsible for full concept learning with the other species was also effective with nutcrackers, allowing direct comparisons to pigeons, rhesus monkeys, and capuchin monkeys. Nutcrackers showed superior initial transfer compared to the other species, despite requiring a similar number of trials as the other species to learn the initial task: 3300, 4000, 3500, 3000 trials, for nutcrackers, rhesus, capuchins, and pigeons, respectively. As the training set was expanded to 32 items and then to 64 item set sizes, the monkeys' transfer closed the gap with the nutcrackers, resulting in all three species achieving full concept learning (i.e., transfer statistically equivalent to baseline performance) at the 128-item set size. Pigeon transfer and concept learning was slower, but nevertheless pigeons achieved full concept learning at the next larger set-size of 256 items. Together, these functional relationships provide much more information about each of the species' concept learning than would be from any single point of comparison. Most remarkable is the qualitative similarity of abstract-concept learning across these different and diverse species, where all species eventually achieved full concept learning, despite the best partial 8-item concept learning by nutcrackers, increasing baseline performance by monkeys, and the larger set size required for pigeons to attain full concept learning.

What might have been responsible for separating the nutcrackers' better initial concept learning from the other species possibly could have been their amazing memory for locations of cached seeds. They bury as many as 30,000 pine seeds in as many as 3000 cache sites, often in new locations yearly, to be recovered when the alpine forest is covered in many feet of snow. Such highly developed location memory depends upon precise relational memory and executive decision making. Those are traits typically associated with episodic memory, folded neocortex, and human primates. So how could such a

differently evolved neural architecture of an avian possibly end up – by chance – producing abstract-concept learning that equals, and initially surpasses, that of nonhuman primates which are more closely related to humans?

### **Same/Different Abstract-Concept Learning by Black-Billed Magpies**

Black-billed magpies provide a test of the nutcrackers' abstract-concept learning skills being based on their amazing seed-cache memory and recovery. Magpies cache much less than nutcrackers, are much more omnivorous, and winter at lower altitudes. Several possible outcomes of such a test can be considered at the outset. If nutcrackers' extensive caching and retrieval was based on their proficient *same/different* abstract-concept learning, then the magpies' *same/different* abstract-concept learning might appear more like that of pigeons. Alternatively, if some other relational-processing skill (e.g., social) were very highly developed in magpies, then their *same/different* abstract-concept learning might even surpass that of nutcrackers. Finally, if *same/different* abstract-concept learning is “baked” into the evolved neural architecture of these two corvid species, then magpies and nutcrackers might be expected to show equivalence in their *same/different* abstract-concept learning.

Ten wild-caught black-billed magpies were tested with the same procedures used to test nutcrackers (Magnotti et al. 2016; Wright et al. 2017). As with the other species, they were trained on 100-trial sessions (50 *same*, 50 *different* trials) until they achieved performance criterion accuracy of 85% (or above) and a minimum of three training sessions. Following acquisition, abstract-concept learning was assessed in six consecutive transfer sessions, each session containing 90 baseline (training) trials and 10 novel (5 *same*, 5 *different*) transfer trials. The cycle of set-size expansion, training for three or more sessions, obtaining 85% correct or better, and novel-stimulus transfer testing was repeated six times for 32, 64, 128, 256, 512, and 1024 item training sets.

Abstract-concept learning, as measured by transfer to novel picture pairs, was 67% correct (chance 50% correct) following initial learning with the initial 8-item training set and increased regularly and monotonically with the training set-size expansions until transfer performance was indistinguishable from baseline (Fig. 6). Magpies and nutcrackers were identical in their substantial transfer following training with the initial 8-item set. Both of these corvid species clearly outperformed pigeons. Magpies, like the nutcrackers, outperformed the monkeys in their initial transfer (partial concept learning) following training with the initial 8-item set. Like monkeys and nutcrackers, magpies attained full *same/different* abstract-concept learning with the 128-item training set size. Comparing learning rates on the initial acquisition, magpies learned in 3500 trials, very similar to the other species (nutcrackers 3300, rhesus 4000, capuchins 3500, and pigeons

3000 trials). Magpie learning rates actually declined as the training set size was expanded from 16 to 1024 items (570, 480, 340, 320, 330, 340, 300 trials) similar to the other species, demonstrating the benefit of progressively better partial concept learning (see also Wright and Katz 2007).

## Concluding Remarks

The functional relationships in Figs. 2, 3, 4, 5, and 6 for these different species embody many of the most important mechanisms and processes of *same/different* abstract-concept learning. As these animals (subjects) experienced more and different items in greater numbers of combinations, they learned to focus on the abstract relationship (*same/different*) between items, ultimately doing so with novel items. By training and testing these different species with the same stimuli and procedures allowed direct species comparisons of how novel-stimulus transfer develops and systematically changes with training set size, including initial transfer with a small 8-item training set and the size of training set where transfer reaches its asymptotic level of full concept learning in the vicinity of 128 training items and more than 4000 exemplars of the *same/different* rule.

These comparisons establish that the magpies' initial transfer (partial concept learning) and full concept learning were not different from nutcrackers, and therefore do not point to the caching and recovery skills of nutcrackers being an advantage in *same/different* abstract-concept learning. The same can be said for the highly developed social skills of magpies. It appears that *same/different* abstract-concept learning is likely "baked" into the evolved neural architecture of nutcrackers and magpies. Mammals, particularly primates, evolved large brains (compared to body weight) with folded neocortex, including the prefrontal cortex, and elaborate temporal lobe structures (e.g., hippocampus plus adjoining parahippocampal cortex), key structures for primate relational processing, abstract-concept learning, and episodic memory (see also chapter

**Same/Different Learning, Fig. 6** Mean percent correct performance of ten black-billed magpies on training (baseline) trials (bold broken purple lines, filled symbols) and novel (transfer) trials (bold purple lines, unfilled symbols) with successively expanded training sets from 8 to 1024 picture stimuli in the *same/different* task and are compared to nutcrackers (thin blue lines, Fig. 5), pigeons (thin green lines, Fig. 4), rhesus monkeys (thin red lines, Fig. 3), and capuchin monkeys (thin orange lines, Fig. 2). Dotted line at 50% correct is chance performance. Error bars are  $\pm$  one standard error of the mean

► **Episodic Memory**). The “bird brain” by contrast has, until only recently, been thought to be primitive. Because most birds fly, light weight is required (hollow and trussed bones, lack of bladder, etc.). Nevertheless, many bird brains (particularly corvid brains) are substantial in size and weight compared to their body weight. Birds have a hippocampus and a caudolateral nidopallium that functions similar to the primate’s prefrontal cortex. Although birds have no folded neocortex, their nodal/nuclear structures have connectivity and speed advantages over folded six-layered neocortex of primates.

How did the so-called primitive “bird brains” become competitive with the more elaborately evolved primate brain to perform thoughts and processes considered of the highest cognitive order, *same/different* abstract-concept learning? (See also chapter ► **Intelligence**) The answer most certainly lies in evolution itself, a multi-million year process. (See also chapter ► **Evolution**) Environmental pressures undoubtedly selected for and shaped these different neural architectures to successfully accomplish many of the same essential and intelligent behaviors for survival, an example of *convergent evolution* where organisms not closely related (not monophyletic) independently evolved similar traits or functions as a result of having to adapt to similar environments or ecological niches (see also chapter ► **Convergent Evolution**). But this example of convergent evolution is comparatively unique because its identification required developing special tests of the cognitive ability (trait) to fully learn a *same/different* abstract concept for this cognitive function to be revealed, unlike other examples where there is a fossil record of an obvious physical trait like wings that provides an obvious function of flying by some insects, birds, and bats.

## Sara Shettleworth

Noam Miller

Wilfrid Laurier University, Waterloo, ON, Canada

Sara J. Shettleworth is Professor Emerita at the University of Toronto. Born in Maine, she completed her undergraduate degree in psychology at Swarthmore College (1965) – where she had her first experiences studying operant conditioning with John Nevin – and her MA at the University of Pennsylvania (1966). She then moved to Canada to complete her PhD at the University of Toronto (1970), where she worked with Jerry Hogan. She remained in Toronto as a professor in the departments of Psychology and Ecology and Evolutionary Biology from 1970 until her retirement in 2009.

In the 1970s, Shettleworth was one of the leading proponents of what became known as “constraints on learning.” In contrast to earlier approaches to associative learning, which assumed that any response an animal was capable of performing could be made to depend on any stimulus it could perceive, Shettleworth and others showed that innate predispositions often limited the associability of particular stimuli and responses. For example, in a series of studies on golden hamsters, Shettleworth showed that the hamsters could be taught to dig or rear up on their hind legs for a food reward, but could not learn to wash their faces for the same reward (even when “encouraged” by being sprayed with water; Shettleworth 1978a). Hamsters could, however, learn to suppress washing their faces in order to avoid a mild shock (Shettleworth 1978b). Findings such as these, which demonstrated that the nature of the stimuli used and the behaviors targeted mattered for learning, suggested to researchers that learning had to be contextualized within the ecology of their subjects. In an influential paper, Shettleworth (1972) argued that such species-specific variation in the “laws of learning” reflects the adaptive significance of various behaviors in the animal's natural environment. The ways in which animals learn, the relationships

they form between stimuli, reinforcers, and responses, depend on the functions of different types of learning in their natural lives.

Closely related to this work, Shettleworth began to push for a closer integration of experimental psychology with ecology, which has been a constant theme of her career. She emphasized the idea that studies of cognitive processes should be tied to the natural behaviors they serve – sometimes referred to as the synthetic approach (Kamil 1987; Shettleworth 1993) – and, conversely, that questions in the emerging field of behavioral ecology could benefit from an exploration of their underlying mechanisms (Shettleworth 2001). These concerns led her to interact and collaborate extensively with both ecologists and psychologists and to show, in numerous publications, how the two fields could gain from a better understanding of each other's methodologies and concerns.

A sabbatical year spent at Oxford University (in 1980) led to a long-lasting collaboration with John Krebs on optimal foraging and to a series of studies on memory and spatial cognition in food-storing birds. Shettleworth, Krebs, and others brought questions on foraging choices into the lab and began to delve into the neural mechanisms that drive them. For example, Shettleworth and others showed that hippocampus size differs between food-storing birds and closely related but nonstoring species (Hampton et al. 1995).

In 1998, Shettleworth published *Cognition Evolution, and Behavior* (an updated second edition was published in 2010). This uniquely comprehensive book has been widely praised for its integration of the ecological and psychological approaches and has become the standard citation for introducing the argument for their closer collaboration. Shettleworth promotes a broad approach to comparative cognition, encompassing everything from perception to communication, together with a suggestion that a detailed study of the elementary mechanisms of behavior can help explain even the most complex of cognitive feats.

Shettleworth has received numerous honors for her contributions to the field of comparative psychology, including a Guggenheim Fellowship (1980), the American Psychological Association

Distinguished Scientist Lecturer Award (1996), a visiting fellowship at the Berlin Institute for Advanced Study (2004), the Comparative Cognition Society Research Award (2008), the Canadian Society for Brain, Behavior and Cognitive Science's Donald O. Hebb Distinguished Contribution Award (2012), and her election to the Royal Society of Canada (2008).

Shettleworth has published over 100 peer-reviewed papers and dozens of popular reports on every aspect of animal cognition. Her experimental studies span the range from pigeons in operant boxes and rats running through mazes to chickadees foraging in artificial indoor forests. Together with her husband Nicholas Mrosovsky, she conducted field studies on sea turtle spatial behavior and migration. In addition to the contributions noted above on foraging, food-storing birds, and constraints on learning, her work has addressed – amongst others – questions of cognitive mapping and spatial learning more generally, episodic-like memory, and geometry learning.

Throughout her career, Shettleworth has thought and written extensively and searchingly on the enterprise of comparative cognition. She has enriched the debates on how different forms of spatial learning may combine to form a cognitive map, on what we can (and cannot) infer about brain processes from comparative studies of behavior, on the importance of studying a wide range of questions and species, and, over and over again, has emphasized the need for a closer connection between the ecological, evolutionary, and psychological approaches to animal behavior. The emergence, over the past 25 years or so, of fields such as neuroethology, cognitive ethology, and cognitive ecology is due in no small part to her influence.

## Sarah "Sally" Boysen

Valerie A. Kuhlmeier  
Queen's University, Kingston, ON, Canada

Sarah (Sally) Boysen's scientific contributions began early in her career when, after obtaining a masters degree in psychology from the University of Oklahoma, she worked as a researcher at the Yerkes Regional Primate Research Center in Georgia. There, along with Sue Savage-Rumbaugh and Duane Rumbaugh, she published a paper in the journal *Science* that suggested that two chimpanzees who were trained to associate symbols with objects in their environment could use these symbols to request items from each other (Savage-Rumbaugh et al. 1978). At the time, the ability of chimpanzees to learn a symbolic language system was a topic of great interest

to many psychologists in the growing field of cognitive psychology. The paper, detailing a novel approach to this topic, provided an opportunity for critical thinking about the cognitive requirements and possible human-uniqueness of language (e.g., Epstein et al. 1980; Savage-Rumbaugh et al. 1980; Terrace 1985).

Sally returned to Ohio, her state of birth (b. 1949), after leaving Yerkes. She received a PhD in Psychology in 1984 at The Ohio State University under the supervision of David Hothersall. Subsequently, as a faculty member of the Department of Psychology at OSU, she directed the Chimpanzee Center until it closed in 2006.

It was at the Chimpanzee Center that Sally and her colleagues conducted groundbreaking research examining numerical abilities in chimpanzees. Sally taught chimpanzees to recognize Arabic numerals by initially training one-to-one correspondence between food pieces and non-edible small objects (e.g., two food pieces on a plate would be matched to a plate that contained two small cotton balls). Over time, the objects were replaced with Arabic numerals, and ultimately the chimpanzees could touch a corresponding numeral for arrays of 0–8 objects (Boysen 1993). This research program also provided one of the first examinations of arithmetic in a nonhuman animal. When one of the chimpanzees, Sheba, was allowed to search a room for hidden food items or numerals in various locations, she was able to return to the starting location and report, by touching a numeral, the summed amount (Boysen and Berntson 1989).

One particularly seminal finding from this work has been the role of numeral use in a reversed contingency task. Boysen and Berntson (1995; Boysen et al. 1996) created a task in which the chimpanzees had to choose the smaller of two piles of candies to receive the larger amount. However, the chimpanzees could not inhibit choosing the larger amount of candy, even though that choice consistently led to a smaller reward. In contrast, when Arabic numerals were used in place of the candy arrays, chimpanzees readily chose the smaller number and subsequently gained the larger amount. The numerals seemed

to represent magnitude symbolically and aided the inhibition of prepotent responses to actual food quantities. This work has proven informative to the study of executive functioning in young children (Carlson et al. 2005) and other ape species (Vlamings et al. 2006).

Other work at the Chimpanzee Center focused on the ability of chimpanzees to recognize the correspondence between a three-dimensional symbol of space (e.g., a scale model) and its real-world referent. Across a series of three studies modeled after seminal work by DeLoache with human children (e.g., DeLoache 1987), Boysen demonstrated that chimpanzees could correctly navigate an enclosure to find a hidden treat after observing a miniature treat being hidden in the analogous location in a scale model. Further, the chimpanzees appeared to recognize the correspondences between individual landmarks in the model and enclosure as well as the spatial relationships of the landmarks (Kuhlmeier and Boysen 2001, 2002; Kuhlmeier et al. 1999). Similar to Sally's research with symbols for quantity, this work has been informative to the study of human cognitive development (e.g., Kuhlmeier 2005; Marsh et al. 2013).

Sally Boysen's role as a leader in field of Comparative Cognition is also apparent in less quantifiable outcomes than number of publications and citations. She was one of the founding members of the Comparative Cognition Society, an international group of psychologists and biologists studying animal behavior and cognition. She has authored a book on animal cognition, written not for other researchers but designed through clear text and graphics to translate science to a broad readership (Boysen and Custance 2009). Earlier in her career, she developed a children's book to introduce chimpanzee behavior to young readers (Boysen 1991).

## Sarah Brosnan

Catherine F. Talbot  
California National Primate Research Center,  
Neuroscience and Behavior Unit, University of  
California, Davis, Davis, CA, USA

### Early Life and Education

Sarah Frances Brosnan was born in La Grange, Illinois, although she grew up in Alexandria, Virginia, and later Baltimore County, Maryland. Throughout her childhood, she was enthralled with exploring the nearby creek and forest. Brosnan always enjoyed sharing her discoveries with others, often bringing critters home for show and tell (much to her parent's chagrin!). Although she had always been fascinated with biology, David Phoebus, her high school biology teacher, was particularly influential in deepening her interests. He structured his classes around experiential learning, focusing on labs and conducting many classes outside the classroom. He encouraged students to write papers on topics that they found interesting. When Brosnan wrote a paper on Dian Fossey, he handed her a few extra books, granted her an extension, and told her to dig deeper – so she did.

Brosnan had the opportunity to further explore various branches of biology when she attended Baylor University in Waco, Texas, where she graduated magna cum laude. She spent 2 years in a limnology lab, studying inland waters, and 3 years in a mammalogy and ecology lab. In the latter, she participated in a number of mark and recapture studies, tracking small mammals across a gradient of old wood forest to an annually mowed field. This experience also led her to working with captive prairie voles, which was

the focus of her undergraduate research. Brosnan received two research grants for her honors thesis in which she compared the reproductive behavior of unrelated females and sisters when they had access to a single male. Her work with prairie voles is what piqued Brosnan's interest in cooperation, as this species is a monogamous, cooperatively breeding species.

These formative experiences inspired Brosnan to apply to graduate programs that studied cooperation. She was much more interested in the mechanisms underlying cooperation than the species per se, but ultimately, she realized that primates were the best model for understanding how individuals decide when to cooperate and with whom. Therefore, when Frans de Waal offered her a position at Emory, she accepted. Brosnan's dissertation research, published in *Nature* (Brosnan and de Waal 2003), was the first to document negative responses to inequity in capuchin monkeys, a behavior hypothesized to support long-term cooperation.

The video demonstrating her experiment quickly became a YouTube sensation and was recently featured on Last Week Tonight with John Oliver (Avery and Perota 2014). The video depicts two capuchin monkeys separated by a clear partition, sitting side by side in front of a human experimenter (Fig. 1). The first monkey exchanges a token (in this case, a rock) with the experimenter. The experimenter rewards the monkey with a cucumber, a food they happily eat in any other context. The experimenter then offers the token to the second monkey, who exchanges the token and receives a grape (a grape!), a highly preferred food among many primates. The first monkey observes this, exchanges the token, and once again receives a cucumber, but this time, she throws it right back at the experimenter! These responses, rejecting the token and refusing to exchange the token or eat the reward (which takes a good amount of self-control), are considered refusals. Capuchin monkeys refuse the token or the reward more often when their partner receives a better reward than themselves but will continue to accept cucumber as "payment" when they both receive a cucumber for their efforts in the control condition.

**Sarah Brosnan, Fig. 1** A monkey in the test chamber returns a token to the experimenter with her right hand while steadying the human hand with her left hand. Her partner looks on (Drawing by Gwen Bragg and Frans de Waal after a video still)

Responding negatively to getting less than a partner has received for the same amount of work has been hypothesized to support long-term cooperation as a means to compare your own efforts and outcomes with that of a partner. Therefore, when you are not getting your fair share, it may be in your best interest to find a new, more equitable partner or work alone. This inspired further research and continues to be the main foci of Brosnan's research.

## Research Interests

Currently, Dr. Brosnan is a professor in the Departments of Psychology and Philosophy and the Neuroscience Institute at Georgia State University. She conducts her research at the Georgia State Language Research Center and the Keeling Center for Comparative Research, where she holds an

adjunct faculty position. By taking a comparative approach to her research, Brosnan is better able to deduce the evolutionary function of particular trait. She examines behavior across the phylogenetic distribution of species, which have evolved in various ecological contexts, to help elucidate whether the behavioral trait in question evolved due to common descent or due to shared selective pressures. In the case of inequity, for instance, several primate species have since been shown to respond negatively to inequity. However, the trait is not universal within primates. This appears to be true even within smaller clades. Within the great apes, for example, chimpanzees (Brosnan et al. 2005, 2010; but see Bräuer et al. 2009) and possibly bonobos (Bräuer et al. 2009) react negatively to inequity, but orangutans do not (Bräuer et al. 2009; Brosnan et al. 2011). Moreover, while Brosnan demonstrated that capuchin monkeys respond to inequity, closely related squirrel monkeys do not (Talbot et al. 2011). Therefore, negative responses to inequity appear to be a convergent trait that evolved due to shared selective pressures. Thus far, about a dozen species have been tested on the inequity paradigm, within and outside the primate order (reviewed in Talbot et al. 2016b). Although several alternative hypotheses have been posited, all of the species that respond to inequity routinely cooperate with non-kin in a variety of contexts such as in group hunts, food sharing, and coalitions and alliances. Thus, the current data suggest that responding negatively to inequity is a convergent trait that evolved in tandem with cooperation.

The comparative approach also lends insight into some of our own, more complex, behaviors not only through understanding their evolution but also the contexts in which they may occur and whether the trait is still beneficial today. The foci of Brosnan's research lie within some of these more complex behaviors generally considered to be quintessentially "human," including fairness and morality. Although she does not expect to observe equivalently complex behaviors in the nonhuman primates she studies, she does expect to observe precursor behaviors, those from which more complex behaviors may have evolved.

Responding negatively to getting less reward than a partner may be a precursor to humans'

sense of fairness. Of course, “fairness” also implies knowing when *others* are treated unfairly as well. Therefore, another line of inquiry for Brosnan is prosocial behavior. That is, behavior that helps another, including situations in which the actor directly benefits themselves (e.g., reciprocity/cooperation) and situations in which the actor does not (e.g., altruism; Brosnan and Bshary 2010). Many primates are seemingly indifferent to helping others even with little to no cost themselves (e.g., Vonk et al. 2008), although there is some evidence that chimpanzees were likely to refuse when they are rewarded more than a partner (Brosnan et al. 2010). This suggests foresight of their partner’s behavior and requires individuals to give up an immediate benefit (e.g., food), in order to stabilize a long-term cooperative relationship. At the very least, it shows that they notice when their partner is rewarded less than themselves.

Fundamentally, morality is a suite of behaviors that help maintain social norms necessary for regulating social life (Brosnan 2017). Precursors to a moral code may include respect for possessions, which several species of primates demonstrate for items such as food, toys, and mates (reviewed in Brosnan 2011). Similar to humans, Brosnan has evidenced the endowment effect in several great apes, in which individuals (somewhat irrationally) prefer to maintain property they currently possess to trading it for something they typically value more in a free-choice context. In contrast to humans, who tend to exhibit this effect in a wide variety of contexts, however, studies in nonhuman primates indicate the effect is limited to food items and tools that can access immediate food rewards, meaning that it is only triggered in evolutionarily relevant contexts (Brosnan et al. 2007, 2012; Drayton et al. 2013; Flemming et al. 2012). Cognitive and behavioral biases, such as the endowment effect, are important to study as they affect decision-making and, at times, contrast the traditional economic view that humans make rational decisions.

Much of Brosnan’s research is rooted in experimental economics, which utilizes game theory to model complex decision-making behavior. Experimental economic games break down strategic

interactions based on other individuals (e.g., cooperation) into simple choices (e.g., accept or reject). This is particularly useful for comparative researchers as it helps standardize methodology across multiple species, including humans. For instance, human reactions to reward distribution in a cooperative interaction are often examined through the ultimatum game in which two players, a proposer and a respondent, must agree on a reward distribution in order to receive a payout. In humans, proposers usually offer a generous portion of the reward to the respondent so that they accept the offer, rewarding both participants. To examine sensitivity to reward distribution across phylogeny, children and chimpanzees were tested in a modified version of the ultimatum game in which proposers could choose between two tokens representing either an equitable or inequitable offer favoring the proposer. Respondents could either accept the offer by exchanging the token for rewards or reject the token/offer. Despite initial preferences for the selfish token, both apes and children made more equitable offers when cooperation of the respondent was required, suggesting continuity between humans and apes in their sensitivity to reward distribution (Proctor et al. 2013).

Brosnan’s Laboratory for Comparative Economics and Behavioral Studies (CEBUS lab) has examined coordination and decision-making through several other experimental economic games across the primate order, such as the assurance game (e.g., Brosnan et al. 2011) and the Iowa gambling task (e.g., Proctor et al. 2014). The CEBUS lab is currently expanding this line of research to include other facets of decision-making including social and ecological influences on decision-making behavior and cognition, more generally. For instance, individual recognition likely impacts decision-making as many species alter their behavior depending on with whom they are interacting. Although several primate species discriminate unfamiliar conspecific faces, little is known about the underlying mechanisms and the role of familiarity (Talbot 2016). Capuchin monkeys tested on a computerized testing paradigm were better able to recognize familiar faces compared to unfamiliar faces, suggesting that

familiarity (or experience with individuals) impacts capuchins' face perception, as it does humans and apes. Still, capuchins performed equally well on familiar in-group and familiar out-group members. Ecologically, this makes sense as capuchins regularly come into visual and physical contact with neighboring groups, which are in competition for food and mates. Quick and accurate recognition of individuals living in neighboring groups may help predict their behavior, potentially avoiding dangerous interactions (Talbot et al. 2016a).

In fact, ecology can dramatically shape cognition. In collaboration with Redouan Bshary at the University of Neuchâtel, Brosnan and colleagues have recently demonstrated that small-brained species, cooperative cleaner fish, can outperform large-brained species (i.e., primates) on a decision-making task. The task was derived from cleaner fish ecology. In the wild, cleaner fish work together to obtain food by removing ectoparasites and dead skin from larger fish that visit their "cleaning station," or territory. Cleaner fish preferentially service visiting clients, those with larger home ranges and access to multiple cleaning stations, over resident clients, those that have smaller home ranges and access to one station. Therefore, the task presented subjects with two choices, one representing an ephemeral food source (i.e., the visiting client) and one representing a permanent food source (i.e., the resident client). As in their natural environment, cleaner fish quickly adapted a maximizing strategy, first choosing the ephemeral food and then the permanent food, permitting access to both rewards. Chimpanzees, orangutans, and capuchin monkeys, however, took much longer to acquire the task, but once they did, they performed equally well in a reversal learning test in which in the opposite choice yielded the largest payoff (Salwiczek et al. 2012). Moreover, adjusting the parameters of the task to be more ecologically relevant to primates improved their performance, matching the performance of the fish in the original study, demonstrating the importance of an ecologically relevant approach to the study of cognition (Prétôt et al. 2016a, b).

Through national and international collaborations and within her own CEBUS lab, Dr. Brosnan

fosters a highly collaborative work environment. Throughout her career, she has demonstrated an incredible ability to approach scientific questions from a number of perspectives (e.g., psychology, philosophy, anthropology, neuroscience, and biology to name a few!), which has ultimately led to her successful and encompassing research program. Dr. Brosnan's contributions to the field of behavior, experimental economics, and animal cognition have thus far evidenced similarities and differences among primates that provide insight into the evolution of decision-making, which may ultimately help us develop interventions and promote better decision-making in ourselves.

Some of the most important contributors in the history of comparative psychology were not themselves comparative psychologists. In fact,

some were not even humans! Four of the most significant contributors to comparative psychology were chimpanzees (*Pan troglodytes*): Sarah, Lana, Sherman, and Austin. These animals served as participants in many behavioral studies, and their data made seminal contributions to a wide range of topics but particularly to the understanding of symbol use and comprehension, both in the communicative domain and also with respect to numerical cognition. The great impact of the four apes on these cognitive competencies, and the relation of symbol-knowledge and numerical judgments to other aspects of cognition, merits special attention.

## Sarah

Fundamental questions about great ape minds were addressed by David Premack and other researchers over the course of their work with a chimpanzee named Sarah. Sarah was wild-born in Africa around 1962 and was brought to the United States when she was less than 1 year old to participate in laboratory-based cognitive testing. She wore diapers, was fed with a bottle, and received an elementary education into the world of psychology in the mid-1960s by testing 5 days a week on matching-to-sample tasks and other paradigms (Premack and Premack 1994; Premack and Woodruff 1978).

At about 4 years of age, Sarah was trained on a series of tasks engineered to teach her a visual language (Premack and Premack 1972). She learned to associate plastic chips of various size, shapes, and colors with nouns, verbs, adjectives, and concepts like “same” and “different.” The training procedure was designed to build on knowledge that the ape might have naturally, for example, about the differences between various foods and about the activity of giving and receiving. Initially, Sarah was simply given pieces of food by an experimenter. Next, a plastic piece (e.g., a pink plastic square, with a thin piece of metal mounted to the back, representing banana) was placed near Sarah with the fruit reward out of her reach. When Sarah moved the plastic piece to a nearby magnetic board – in effect,

communicating “give” the food – Sarah was rewarded with the corresponding fruit. After Sarah had learned this sequence, a different type of fruit morsel and a different plastic piece (e.g., blue triangle, meaning “apple”) were introduced. After this association was formed, another fruit/plastic-piece pair was introduced, and so forth, as new symbol-referent associations were established. This training formed the backbone of Sarah’s vocabulary. Subsequently, additional layers of complexity were added. Presenting the correct plastic piece was made insufficient for reward unless an additional plastic piece (glossed as “give”) was presented as well. When other names were introduced, rewards could only be received by adding more pieces to the magnetic board (e.g., “[Experimenter] Give Apple Sarah”). Conversely, Sarah was also asked to “read sentences” on the magnetic board and respond appropriately. Premack and Premack (1972) described the example “Sarah Insert Apple Pail Banana Dish” to which Sarah responded by placing the apple in the pail and the banana on the dish. Complex sequences such as these required Sarah to know the objects or actions associated with each plastic chip and also to be sensitive to the relation between symbols. With the introduction of relational-concept symbols – plastic pieces that meant “name of,” “not name of,” “same,” or “different,” for example – training and testing of meanings could be done outside the context of social exchange.

These experiments demonstrated flexible learning by Sarah of about 130 “words” as well as impressive performance on tests of relational concepts. Premack and Premack (1972) compared Sarah’s “language ability” to that of a 2-year-old child. However, the extent to which Sarah’s performance should be understood as language learning is in question. Savage-Rumbaugh et al. (1980a) described Sarah’s performance in strictly associative terms and identified a number of components of experimental design that challenged what Sarah was really learning. For example, when Sarah needed to name multiple nouns to receive reward (“[Experimenter] Give Apple Sarah”), many components of the required sequence (“[Experimenter],” “Give,” “Sarah”) were

remained constant within each session. This and other design issues make Sarah's actual "vocabulary" difficult to quantify and interpretations of her actions as revealing language learning as tenuous.

Premack and Woodruff (1978) attempted to test Sarah's awareness of other minds. Sarah viewed video clips of an actor struggling with a relatable (to a chimpanzee) problem. For example, the actor might be unable to reach a banana when the space between actor and banana was obstructed or if the banana was suspended over the actor's head. Sarah's task was to choose between a photograph that showed the correct solution to the actor's problem (e.g., climbing on top of boxes to reach the overhead banana) and one that would not solve the actor's problem. Sarah was highly accurate on this task and on a second task with problems not applicable to a chimpanzee's ecology (e.g., plugging in a phonograph or connecting faucet and hose). This and other early studies of how one primate perceives the behavioral and cognitive capabilities of another (Menzel 1974; Menzel and Johnson 1976) helped to initiate an entire field of psychological and philosophical scholarship on the study of nonhuman animal "theory of mind" – as well as an enduring fascination with what the minimum cognitive mechanisms are that could account for Sarah's performance (see Call and Tomasello 2008; de Waal 2011).

Sarah continued to participate in laboratory-based cognitive studies including those on numerical ability (Woodruff and Premack 1981), spontaneous categorization (Matsuzawa 1994), responding to other individuals' knowledge states (Povinelli et al. 1990), the reverse-reward contingency paradigm (Boysen and Berntson 1995), conceptual matching to sample (Thompson et al. 1997), and many more. Some of these findings serve to illustrate a critical but underappreciated value of research with chimpanzees like Sarah, Lana, Sherman, and Austin: Their "failures" (e.g., Limongelli et al. 1995) are as important and informative as their successes, in that they help to reveal cognitive limitations of nonhuman animals – even the most highly educated apes on the planet. Sarah's contributions to the emerging field of comparative cognition in the 1960s–1980s

were extensive, long-lasting, and critical to the now well-established understanding of the sophistication of the chimpanzee mind.

## Lana

Lana was born on October 7, 1970, at the Yerkes Regional Primate Research Center, Emory University, Atlanta, GA. She was assigned (along with a young orangutan named Biji) to a new behavioral research program under the direction of Duane Rumbaugh to determine whether apes could learn and use a human-like language. Rumbaugh named the initiative the Language ANalog (LANA) Project after its focal 2-year-old participant.

A computer-based keyboard was designed that held visuographic symbols called "lexigrams" – each representing a word. Pressing a key caused the corresponding symbol to appear on a series of projectors and to be recorded on the data transcript, and a grammar for combining these symbols into stock "sentences" was established. Grammatical sentences led to computer responses (e.g., delivery of juice to the utterance "PLEASE MACHINE GIVE JUICE PERIOD," where "PLEASE" and "PERIOD" were stock lexigrams used to start and end such utterances). This so-called "Yerkish" language was also used by Lana to interact with human researchers (particularly Dr. Timothy Gill, then a graduate student and Lana's primary teacher) when they communicated with her.

Lana was initially shaped to touch the keys and to string them together into two- and three-symbol responses, after which she began to learn the referents of symbols that represented objects (e.g., juice, apple, movie), actions (e.g., give, tickle, put), and actors (e.g., machine, Tim, Shelly). She used the keyboard to make requests, to ask questions, to name objects, and to comment on her surroundings. After the first year, Lana's keyboard had expanded to 75 symbols, of which about 50 were typically backlit and active at any point (Rumbaugh et al. 1974). The positions of the lexigrams were changed frequently to ensure that Lana was attending to the symbols rather than the

locations. Lana was reported to make few errors in lexigram use, and she even came to innovate a way of aborting sentences in which the wrong key had been pressed, by immediately using the PERIOD lexigram to terminate the utterance. She was greater than 90% accurate, both in completing sentences that were started validly and also in aborting sentences with errors at the beginning (Rumbaugh 1977).

Lana's remarkable performance garnered considerable attention, both complimentary and critical, in the scholarly literature and the popular media. Lana learned the meanings of at least 140 symbols. Although many of her stock-sentence utterances were formulaic requests (as indeed is true in human language) criticized as chains of conditioned responses, she also innovated novel lexigram combinations to describe new objects and used legal variations in sentence structure to make the same requests. Sentence length increased as the number of available symbols increased. Project scientists concluded that the frequency of utterances that were purely imitations was low (Hillix and Rumbaugh 2004) and that Lana was generally using the lexigrams meaningfully. Beran et al. (2000) tested Lana's long-term memory for lexigrams and found that Lana showed excellent retention of symbol meanings for lexigrams she has not seen for two decades! Despite the debate that surrounded the question of whether Lana "had language," with the publication of *Language Learning by a Chimpanzee: The LANA Project* (Rumbaugh 1977), her pioneering contributions to the understanding of symbol acquisition through keyboard use received full discussion, as did the potential led to widespread application of the computer-based communication system for nonspeaking human children with profound language impairments (see also Ronski et al. 1985).

In 1981, Lana moved to Georgia State University's Language Research Center (LRC), where she continued to be the focus of noninvasive cognitive and behavioral research. Lana's contributions were not limited to the language domain. She was also taught to enumerate and to indicate quantities using Arabic numerals. Using the computerized test system (also called the

"Rumbaughx" to parallel other classic apparatus like the Skinner box, Thorndike problem box, and so forth; see Washburn et al. 2013), Lana manipulated a joystick so as to move a cursor on a computer screen, "counting out" stimuli corresponding to the number of items represented by a target numeral (Beran and Rumbaugh 2001; Rumbaugh et al. 1989). She remained active and productive in research until her death at the age of 46 years, participating voluntarily in many other computerized and manual research studies, including investigations of learning, perception, attention, memory, cognitive control, metacognition, language, numerical cognition, and other topics. By current estimates, Lana produced data for more than 200 journal articles and chapters and has been studied by more than 100 scientists from various fields. Because her performance with lexigrams was critical in the formation of the LRC and the resources it has provided to scholars interested in primate cognition, Lana has also contributed indirectly to countless research areas with monkeys, human adults, and children (both typically developing and developmentally delayed).

## Sherman and Austin

Inspired by the success with Lana, but seeking to address some limitations of the LANA Project, Sue Savage-Rumbaugh and her research team (including Duane Rumbaugh, Sally Boysen, and others) initiated a new ape-language project in 1976. Project scientists were increasingly convinced of the importance of the social functions of language. Lana had been trained to communicate with a computer and with human researcher. To encourage social communication between conspecifics, the new project obtained four chimpanzees (Austin, Erika, Kenton, and Sherman) from the Yerkes Center. Ultimately, the demands of raising four apes in language training proved too demanding for the research team, and so the effort was focused on just two of the chimpanzees. Sherman (1973–present) was 2.5 years old when symbol training began; Austin (1974–1996) was 14 months younger.

The computer-based keyboard and lexigrams developed for the LANA Project were introduced to Sherman and Austin (S&A), including many new lexigrams to represent the many indoor and outdoor areas available to these apes at the LRC. Whereas Lana had been trained to produce strings of lexigrams, defined by the rules of Yerkish, to obtain desired outcomes, the foci of the Animal Model Project with S&A were interindividual communication and comprehension or understanding of the symbols (Savage-Rumbaugh et al. 1980a). Tests were developed in which S&A might solve problems using the lexigram keyboard that could not be solved without symbol-based communication (Savage-Rumbaugh et al. 1978). For example, Austin might see food locked in a box but have no key; Sherman might have access to the key, among many other objects, but not the box. Using the lexigram keyboard (but not without it), Austin could request the key from Sherman, who in turn would receive a portion of the reward from Austin for his assistance.

The focus on what the chimpanzees understood about the symbols is illustrated by an important categorization study (Savage-Rumbaugh et al. 1980b). S&A were trained to sort six specific items into two bins: foods versus tools. The animals were then tested for generalization to new items and passed this transfer test successfully. The apes were then shown photograph of exemplars, which they were able to sort into the food or tool categories (even though the photographs themselves were all inedible). The apes were then tested with lexigrams and were able to pass novel transfer tests by sorting symbols that represented foods into one bin and lexigrams representing nonfoods into the tool bin. Combined, S&A responded correctly on 32 of 33 trial-1 generalization tests, showing that they understood the lexigrams to represent specific referents that were not present at that time and place.

Like Lana, S&A moved to the LRC in 1981 and continued to participate in studies of language and new research on numerical cognition. For example, they were the focal animals in a series of studies on summation (e.g., Rumbaugh et al. 1987). Using a modified Wisconsin General Test Apparatus, the

apes were presented with pairs of wells, with each well containing some number of chocolates. The apes could select either pair of wells, but to optimize their choices, they needed to determine which pair had the greater total number of candies. S&A selected the greater sum on more than 90% of the trials, and their accuracy could not be explained by lower-level strategies like “choose the pair with the largest single number” or “avoid the pair with the smallest single number.”

S&A demonstrated many other competencies in the domain of numerical cognition, learning, memory, and problem-solving. Sherman remains highly motivated to participate in behavioral research and has been a star performer in tests of memory, delay of gratification, metacognition, and visual perception (e.g., Beran et al. 2015 for a review). His ongoing contributions to science illustrate the irreplaceable value of longitudinal cognitive research with nonhuman animals, in which new abilities may emerge on the scaffolding of previous training and competencies. Sherman’s lifetime of research participation provides unique opportunities to understand what language training allows an organism to do cognitively that it could not do otherwise and what behavioral competencies do not benefit from experience with symbols. The contributions of all of these chimpanzees serve to remind us that although their rearing histories are unique, and the efforts to work with them for so many decades were massive, the results were transformative for understanding more about chimpanzee minds and more about our own.

## Definition

Maintenance of energy balance is a critical feature for species survival and elegant physiological mechanisms have evolved throughout the years in order to maintain homeostasis (Woods and D'Alessio 2008). One of these mechanisms is satiation, defined as the process that leads to the termination of eating, thus plays an important role in the system of appetite control. As a physiological component of humans, satiation acts as an energy regulator, manifested as a sensation during food consumption, the main roles of which are to signal when enough energy has been consumed and consequently, leads to the cessation of eating.

Normally, satiation is accompanied by satiety, which is the persistent sensation of fullness post ingestion. Satiety has the important role of signaling that no further energy intake is necessary until feeling hunger again (Benelam 2009; Blundell 1999). Satiation primarily depends on the volume of food ingested and is not always dependent on caloric value. Foods that are rich in fibers and fat and/or fibers and protein are greater in volume and deliver the “fullness” sensation faster than foods rich in fat, other carbohydrates, and protein only.

## Physiological Mechanisms of Satiation

Maintenance of energy balance and a healthy body weight has been critical to human survival, and sophisticated physiological mechanisms exist in the body to maintain homeostasis (the maintenance of a constant internal environment in the body) (Woods and D'Alessio 2008). The control of energy intake is vital to energy balance, and satiation and satiety are part of a complex system of appetite control, which regulates how much we consume. The process leads to the termination of eating, which may be accompanied by a feeling of satisfaction, satiety – the feeling of fullness that persists after eating, potentially suppressing further energy intake until hunger returns.

## Gastric and Intestinal Mechanisms

Satiation is influenced by a great number of body mechanisms, including gastric distension and hormone action. Once food or drink is ingested, a cascade of physiological events is triggered as a response and a series of inhibitory signals are released to stop food consumption and prevent further ingestion until another meal is needed. These signals are part of the satiety cascade and act together with satiation processes to regulate energy balance.

When food reaches the gastrointestinal tract, stomach distension is signaled to the brain through the afferent fibers of the vagus nerve which project to the nucleus of the solitary tract (NTS). From the NTS, these short-term signals are integrated in the hypothalamic area, along with other information related to ingestion sent from different regions of the body, such as from the adipose tissue. As digestion continues, the food is released to the small intestine for nutrient absorption. The intestine also communicates with the brain regarding the amount of nutrients consumed which contributes, in part, to satiation and satiety (Blundell et al. 1987). During this process, hormones such as cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), peptide YY, and pancreatic polypeptide (PP) are released. CCK is the main hormone responsible for meal termination and satiation, whereas the others previously listed play a role in satiety, by

sensing fullness and communicating to the brain that no further ingestion is necessary (Wynne et al. 2005).

In a postingestion state, the adipose tissue and pancreas release leptin and insulin, respectively, and they both act in the long-term modulation of satiety and satiation based on the amount of fat obtained from the food and the amount that is stored in the body. All signals are integrated in the brain to affect energy intake and expenditure, and a reciprocity between the adipose tissue, the gut, and the brain is necessary for appetite regulation.

## Brain Mechanisms

The brain is responsible for integrating the information received from the gut regarding satiation and satiety, and the arcuate nucleus of the hypothalamus is the region that was identified to play a role in homeostatic balance over six decades ago. Such integration is carried out by anorexigenic (appetite suppressing) and orexigenic (appetite stimulating) neuronal populations within the hypothalamic area, which translate signals of satiation and satiety to modulate energy intake thereby maintaining energy balance (Morgane and Jacobs 1969). Regarding the orexigenic pathways in the hypothalamus, these are comprised by agouti-related peptide (AgRP) and Neuropeptide Y (NPY) expressing neurons, which are known to increase appetite and consumption, whereas the anorexigenic pathway is comprised of pro-opiomelanocortin (POMC) neurons, the main neuronal population involved with appetite suppression in the arcuate nucleus of the hypothalamus (Balthasar et al. 2004; Sohn 2015). This brain region also contains the neurotransmitters glutamate and GABA, which have been shown to modulate feeding behavior and can influence, in part, the functioning of other neuronal populations in the hypothalamus. The function of the specific neuronal populations in the arcuate is tightly regulated and is essential for energy balance; any disturbances can lead to obesity or starvation. Furthermore, the brain also receives information from the substances being digested, which can directly affect neurotransmitter synthesis and, therefore, strongly influence circuits that play a role in homeostasis.

## The Impact of External Factors on Satiation

Satiation can be primarily influenced by many sensory and cognitive factors, such as the expectation prior consumption, cues and contexts associated with food, the smell, taste and texture of the food, and once the food is ingested, a series of postingestive mechanisms. Although everyone has internal mechanisms to control appetite, in some cases people ingest food when they are sated and not in a negative energy balance, and that can be attributed in part to external factors. Both satiation and satiety can be strongly influenced by environmental factors, such as the variety of food available and portion size, physical activity, sleep, stress, eating in the presence of a television, social situations, eating along with alcohol consumption, and palatability. The effect of palatability has been widely studied in eating disorders and obesity. The intake of highly palatable foods is typically pleasurable and activates reward pathways in the brain. The activation of these hedonic systems can override the effect of satiation and long-lasting signaling of satiety, which is a key driver of eating beyond energy requirements, i.e., overeating (Bellisle 2003; Read 1992).

The consumption of food and drink to provide energy is a voluntary behavior, and, despite the existence of sophisticated physiological mechanisms to match intake to requirements, humans often eat when sated and sometimes refrain from eating when hungry. Thus, there are numerous influences on eating behavior beyond satiation and satiety. These include: the portion size, appeal, palatability, and variety of foods and drinks available; the physiological impact on the body of physical activity and sleep; and other external influences such as television viewing and the effect of social situations.

## Definition

Savanna is defined as a tropical or subtropical vegetation type that has a continuous grass cover occasionally interrupted by trees and shrubs.

## Introduction

Savanna represents a vegetation type that grows under hot, seasonally dry climatic conditions

and is characterized by an open tree canopy (i.e., scattered trees) above a continuous tall grass understory (the vegetation layer between the forest canopy and the ground) (Fig. 1). The coexistence of trees and grasses is common to savanna ecosystems, with the ground layer dominated by shade-intolerant C<sub>4</sub> grasses. This layer persists because woody perennial plant species growth is limited below its rainfall-based potential by disturbance, including periodic grass fires and browsing (Bond 2008; Sankaran et al. 2005). The equilibrium between these two life forms (woody tree layer and grasses) influences both plants and livestock production and has profound impacts on several aspects of ecosystem functioning, including carbon (C), nutrient, and hydrological cycles.

Tropical savannas are very common and cover approximately 20% of the total terrestrial surfaces. The importance of the savanna can be understood by the fact that these are the home for one-fifth of the world's total population. But unfortunately, these ecosystems are continuously subject to intense human exploitation by conversion to agricultural and grazing land (Hoffmann et al. 2002). They are the most frequently and extensively burnt ecosystem on Earth, accounting for around 44% of global C emissions by fires (van der Werf et al. 2010). Dry-season fires, fuelled by dried grasses, may kill some trees, especially the more-vulnerable young saplings, and therefore, their severity also greatly influences the nature of savanna vegetation. Savannas are of different types and occur under a wide range of bioclimatic conditions, and it is likely that the importance of different processes in regulating woody cover may vary in different savanna regions. Ecosystems with these characteristics are found throughout the tropics in all continents particularly in the Americas (North and South), Africa, Australia, India, the Myanmar-Thailand region in Asia, and Madagascar. Tropical savannas occupy the greater area of the southern continents – some 65% of Africa, 60% of Australia, and 45% of South America. Despite their vast area, wide distribution, and potential importance in terms of livestock and crop production, savanna has not enjoyed the intensity of research interest

**Savannah, Fig. 1** A typical savanna vegetation with scattered tree in continuous grassland (photo credit: Gretchen Walters/IUCN)

devoted during the last several decades to the deserts, rainforests, and mediterranean regions. In fact they are probably the least understood of the world's major terrestrial ecosystems. This chapter will provide the information about the savanna ecosystem, their advantages in terms of ecosystem services, and current threats to this diverse and one of the most successful ecosystems.

## Origin and Spread of Savanna

Explaining the geologically rapid appearance and spread of  $C_4$  savanna ecosystems onto the ecological stage remains a major scientific challenge. During the late Miocene (Miocene is an epoch of Neogene period during the Cenozoic era) around 6–8 million years ago, savannas and  $C_4$  grasslands became prominent features of tropical landscapes as a result of a rapid global increase in the dominance of  $C_4$  grasses (Edwards et al. 2010). The leading hypothesis states that atmospheric  $CO_2$  concentration fell below a critical threshold during the Miocene, where the photosynthetic efficiency of  $C_3$  plants dropped below that of their  $C_4$  counterparts (Cerling et al. 1997). However, subsequent evaluation of this “ $CO_2$  starvation hypothesis” with multiple atmospheric  $CO_2$  proxy records (Royer et al. 2001) has

consistently failed to show the anticipated decrease at any time during the entire 18 Ma duration of the Miocene. In fact, declining  $CO_2$  had already breached a critical threshold some 20 Ma earlier in the Oligocene, an event linked with the evolution of the  $C_4$  pathway. Declining atmospheric  $CO_2$  concentration is, therefore, unlikely to be the sole driver of worldwide  $C_4$  savanna expansion. Consequently, the well-documented rise of this extraordinarily successful terrestrial biome continues to demand explanation (Beerling and Osborne 2006).

The second hypothesis found climate change as an important factor for the expansion of savanna. Increased aridity in the late Miocene has been shown to cause the retreat of forests in North America and Eurasia, allowing grasslands to spread in their place. The South American fossil record provides evidence of well-developed vegetation, rich in grass and thought to be equivalent to modern savanna, being established by the early Miocene Epoch, about 20 million years ago. Climate across the world became steadily cooler during that period. This drop in atmospheric temperature leads to decrease in ocean surface temperature and therefore reduced water evaporation, which ultimately slowed the water cycle, with less cloud formation and precipitation. This climatic condition significantly affected the vegetation of mid-latitude

regions, lying between the wet equatorial areas and the moist cool temperate zones. The main areas in which savannas originated in response to that long-term climatic change include tropical America, Africa, South Asia, and Australia which were already separated from each other by ocean barriers by that time. Plant migration across those barriers was stopped, and the details of the emergence of savannas on each continent varied. In each area different plant and animal species evolved and adapt to occupy the new seasonally dry habitats. In temperate region, savannas became much more frequent, at the expense of forests, during the long, cool, dry intervals – contemporaneous with the ice ages – or glacial intervals, of the Pleistocene Epoch (2.6 million to 11,700 years ago). Studies based on fossilized pollen in sediments from sites in South America, Africa, and Australia enable strong support for this view.

Apart from atmospheric CO<sub>2</sub> decline and climate change, there is another hypothesis that explains the role of mammalian herbivores in creating open canopy. Many experimental and observational studies have shown that mammals have the capacity to create open canopy by reducing tree biomass whether in the tropics or temperate or boreal regions. Browsing animals either of megaherbivores (>1000 kg) or mesobrowsers (4–450 kg) such as deer, antelope, and caprids are primarily responsible for open habitats and are very effective at preventing woody plant species from crossing the “browse trap” line and growing into larger size classes. They have also been implicated as agents maintaining open ecosystems and preventing forest development. Today, large number of research is still required to connect the exiting information and to explain the origin and spread of the savanna ecosystem.

### Climatic Condition that Support Savanna

The climatic conditions are warm to hot in all seasons, but significant rainfall occurs only for few months each year and about October to

March in the Southern Hemisphere and April to September in the Northern Hemisphere. Mean annual precipitation is generally 80–150 cm, although in some central continental locations it may be as low as 50 cm. The dry seasons are typically longer than the wet season, but it varies considerably, from 2 to 11 months. Savanna climate is similar to equatorial climate as regards temperature, but the annual range of temperature ranging between 3 °C and 8 °C is greater than in the equatorial climate. The dry season in savanna grasslands is cooler than the wet season by few degrees, and mean monthly temperatures are about 10–20 °C in the dry season and 20–30 °C in the wet season. The prevailing winds in tropical grasslands are the trade winds. They are easterlies, blowing from east to west. These winds have an enormous impact on the rains in this climate zone. For instance, rainfall in the savanna decreases from east to west. They are also the cause of the alternating dry and wet seasons. During summer, onshore winds bring rain, and in winter, offshore winds keep the savanna region dry. The trade winds are strongest in summer.

### Types of Savanna

Savanna can be subdivided into different categories depending on length of dry period or the physiognomy of the landscape. Depending on the dry period length, it may be dry (dry period last for 5–7 months), wet (dry period last for 3–5 months), or semiarid savanna (Table 1).

On the physiognomy basis, savanna can be subdivided as woodland, tree, shrub, or grass savanna as it is dominated by trees and shrubs, scattered tree, shrub, and grasses, respectively.

**Savannah, Table 1** Classification of savannas according to amount of rainfall received per year, length of dry season

| Types of savanna | Mean annual rainfall (mm) | Length of dry season (month) |
|------------------|---------------------------|------------------------------|
| Moist savanna    | 1000–2000                 | 3–5                          |
| Dry savanna      | 500–1000                  | 5–7                          |
| Semiarid savanna | 250–500                   | 7–10                         |

## Biological Diversity of Savanna

### Flora

Tropical savannas have high species diversity, especially when compared with temperate grasslands and dry tropical woodlands. Different groups of plants are prominent in the savannas of different regions. In the drier regions of East Africa, acacias (*Acacia*) and bush willows (*Combretum erythrophyllum*) are the most common savanna trees, with thick-trunked baobabs (*Adansonia digitata*), sturdy palms (*Borassus* sp.), or succulent species of spurge (*Euphorbia*) being conspicuous in some areas. In the drier savannas in particular, there is often a wide diversity of spiny shrubs. Among the most prevalent grasses are species of bluestem (*Andropogon*), thatching grass (*Hyparrhenia*), and kangaroo grass (*Themeda* sp.). In wetter savannas, *Brachystegia* trees grow above a 3-m-tall understory of elephant grass (*Pennisetum purpureum*). The most-common West African savanna trees are in the genera *Anogeissus*, *Combretum*, and *Strychnos*.

At temperate latitudes in Australia, the flora of the savanna resembles that of other types of sclerophyllous vegetation. Sclerophyllous characteristics like thickened cuticle, rolled margins, dense indumentum, high specific leaf weight, and increase in volatile oils are common to savanna genera. Most Australian savanna trees are evergreen, surviving the dry season not by dropping their leaves but by reducing water loss from them. The dominant trees of savannas in Australia and southern New Guinea are various species of *Eucalyptus*, *Acacia*, *Albizia*, *Cassia*, *Bauhinia*, *Casuarina*, screwpine (*Pandanus*), and other tall shrubs also common. Baobabs (*Adansonia gregorii*) are the most common, and conspicuous savanna trees in parts of northwest Australia indicate its Gondwana link. Tall spear grass (*Heteropogon*), annually growing *Sorghum*, or the shorter kangaroo grass (*Themeda*) dominates the understory of large areas of moist savanna. The prickly spinifex grasses (*Plectrachne*, *Triodia*) are prominent in more arid regions. Most trees and shrubs of the Australian savanna are markedly sclerophyllous.

Small patches of monsoon rainforest and other types of vegetation occur locally within mainly savanna regions, surviving in places that have some degree of protection from the dry-season fires.

Across large parts of the tropical American savannas, the most common broad-leaved trees are *Curatella americana*, locust berries (*Maricao cimarrons*), and *Bowdichia* sp., their place being taken in some seasonally waterlogged sites by the palms *Copernicia* sp. and *Mauritia* sp. Grasses include species of cutgrass (*Leersia*) and bahia grass (*Paspalum notatum*). In Argentina the most common woody plant is the bean relative *Prosopis* tree.

In India the savanna vegetation of most areas has been extensively altered by human activities, which also have expanded its range. Where least altered, Indian savannas commonly consist of thorny trees of *Acacia*, *Mimosa*, and *Ziziphus* growing over a grass cover consisting mainly of *Sehima* and *Dichanthium*, the latter also referred to as bluestem. The savannas of Asia and tropical America, unlike those of Africa and Australia, are best considered as attenuated rainforests, their natural biotas having strong affinities with those of the wetter environments nearer the equator in the same regions. Trees in those savannas are usually deciduous, their leaves falling during the dry season.

### Fauna

Savannas provide habitats for a large number of wild animal species, some of which help the vegetation through grazing, browsing, pollinating, nutrient cycling, or seed dispersal. Many regions of savanna are managed today to maintain large grazing mammals, such as the native fauna of Africa or the cattle used for commercial production in large areas of Australia and South and Central America. Less spectacular but nevertheless very important are the small invertebrates, for instance, grasshoppers and caterpillars are among the keen consumers of the understory foliage, and termites are significant consumers of dead plant material, including wood. The role and importance of termites in savanna as ecosystem engineers in tropical ecosystems are functionally

similar to earthworms in temperate areas. Termites are important for soil turnover, and in symbiosis with *Termitomyces* sp. belonging to fungi, *Macrotermes* termites transform organic material into plant-available inorganic forms, creating favorable sites for tree and forb (broad leave herbaceous plant species) establishment (Van der Plas et al. 2013). Thus termite mounds behave as nutrient hot spots changing the spatial distribution of resources on a landscape scale (Jouquet et al. 2011). Animals of savanna ecosystems have adapted to surviving the seasonal variations in their food supply. Many bird species (especially in Africa) and many mammals are seasonal migrants, occupying savannas during and immediately after the wet season when vegetation is lush and food abundant. They move elsewhere for food as the green parts of the plants disappear later in the dry season. This seasonal migration benefit birds by moving between environments where breeding is successful and environments where survival during the non-breeding season is relatively easy. The significant seasonal contrast in availability of plant food is less marked belowground where roots, tubers, and other subterranean organs commonly make up a large proportion of the total plant biomass. For example, up to four times of aboveground component has been found belowground in some West African study sites, especially in the dry season. It is not surprising, therefore, that most savanna invertebrates not only termites but also many other arthropods and earthworms spend most of their life span below the ground. The large mammals basically are part of a grassland community, despite the presence of low trees in their environment. Most animals depend on the grass component of the vegetation for their food either directly, as do the herbivorous buffalo, zebra, gnu, hippopotamus, rhinoceros, antelope, etc., or indirectly as is true of the carnivores like lions, leopards, etc. and scavengers such as vultures and marabou stork (*Leptoptilos crumenifer*) that feed primarily on those herbivores. Only a small number, including the giraffe (*Giraffa* sp.) and elephant (*Loxodonta* sp.), rely on foliage or fruit from the often thorny woody tree species. Large animals are relatively uncommon in savannas of Australia

and are represented mainly by several species of the family Macropodidae, such as kangaroos and wallabies. However, in that area, a wide variety of very large mammals and reptiles became extinct million years ago. Their place today is taken by animals, both domesticated and wild, which have been introduced by humans including mainly cattle but also horses and, more locally, camels, donkeys, Asian water buffalo (*Bubalus bubalis*), etc.

## Factors Regulating Savanna Ecosystem

The structure of the savanna ecosystem is maintained and regulated by the environmental factors such as moisture, nutrient level (resource-based factor), herbivory, and fire (disturbance-based factor) (Fig. 2). These factors restrict the growth of the woody cover in a different way (detail given later on) and maintain one of the most successful ecosystems. Further the physiognomy of savanna at given site is influenced by the edaphic and climatic determinants which control the potential growth and survival of trees as well as grasses.

### Fire

Fire is an inevitable consequence of the annual cycle of profuse herbaceous production during the wet season followed by burning of this material in the dry season. Savanna fires are virtually all surface fires, consuming the highly flammable herbaceous layer. Crown fires rarely occur as the fuel loads are dominated by fine fuels (grass and leaf litter) and the foliage of savanna trees and shrubs tend to be of low flammability. In several studies it has been found that fire restricts the perennial woody tree species to establish by burning the young saplings. Perhaps the most compelling evidence that fire controls the distribution of forest is the results of fire-exclusion experiments that have shown forest species invading fire-protected savanna, especially in high rainfall areas with a complete biome shift from grassy to closed canopy sometimes occurring within a few decades (Woinarski et al. 2004). Some plants survive over fire, for example, those buds located

**Savannah, Fig. 2** Schematic diagram showing the regulation of savanna vegetation through resource- (bottom-up effect) and disturbance (top-down effect)-based control

underground or beneath thick bark that provides fire protection; regeneration quickly takes place from those shielded structures when condition becomes favorable. Other plants can reproduce effectively from seeds shed onto the scorched ground in the wake of wildfire. Such plants benefit from burning and become more abundant than the fire-sensitive plants that occur in areas of frequent burning. Among those plants, *Eucalyptus* trees, which dominate most areas of Australian savanna, are important. Other trees in Australian savannas, for instance, cypress pine (*Callitris*), are highly drought-tolerant, though fire-sensitive. Today *Callitris* is restricted to sites such as gorges and rocky outcrops where there is some protection from fire. Similar patterns are recognizable in other regions. For example, in northern Nigeria, thickets comprising a few fire-sensitive rainforest trees such as *Diospyros*, figs (*Ficus*), and *Tamarindus* grow on rocky knolls lacking grass. Those rocky “islands,” protected from fire and cattle, are surrounded by expanses of grazed and frequently burned savanna. Where plots of African savanna vegetation are protected from being burned, they tend to revert quickly to deciduous forest.

### Herbivory

The grazing animals also can alter the balance between woody plants and grasses in a savanna – in either direction, depending on their feeding habits. For example, grass-eating mammals may overgraze and push the grass toward local extinction. However, even high populations of those grazers cannot eliminate tall woody plant species, whose upper branches are out of their reach. Subsequent regeneration will favor the woody plants, which will become denser and shift the profile of the vegetation from savanna to forest. Megaherbivores can have the reverse effect if their populations increase. For instance, a steady rise in the elephant population between 1934 and 1959 in Virunga National Park, Congo (Kinshasa), led to an increase in the destruction of woody plants and transformed a heavily wooded savanna into a grass savanna with very few trees. Grazing (consumption of grass) can favor woody vegetation by reducing grass biomass, thereby reducing both tree grass competition and fire frequency and intensity, which have been shown to increase tree recruitment and growth. Such a grazing effect explains bush encroachment following heavy overgrazing by

domestic stock (van Langevelde et al. 2003). Bush encroachment is the suppression of palatable grasses and herbs by encroaching woody species often unpalatable to domestic livestock. Therefore, bush encroachment reduces the carrying capacity for livestock. Conversely, browsing (consumption of woody plants) can limit woody plants, maintaining open, grassy systems. Indeed, browsing has been shown experimentally to reduce woody plant abundance in savannas (Augustine and McNaughton 2004), largely due to its strong negative effect on height growth, especially in conjunction with fire.

### Edaphic Factor

Soil fertility is generally rather low in savannas but may show significant small-scale variations. It has been studied in Belize and elsewhere that trees can play a significant role in drawing mineral nutrients up from deeper soil. The leaves and other tree litter drop to the soil surface near the tree, where they decompose and release nutrients. Soil fertility is thereby greater near trees than in areas between trees. An unusually large proportion of dead organic matter approximately 30% is decomposed through the feeding activities of termites. Thus, a significant proportion of released mineral nutrients may be stored for long periods in termite mounds where they are not readily available to plant roots. In savannas of Thailand, it has been shown that soil fertility can be markedly improved by mechanically breaking up termite mounds and spreading the material across the soil surface. In Kenya, old termite mounds, which are raised above the general soil surface, also provide flood-proof sites where trees and shrubs can grow, with grassland between them, forming the so-called termite savanna. The biota of savannas reflects their derivation from regional biotas; therefore, species vary between regions.

Savanna plants annually experience a long period in which moisture is inadequate for continued growth. Although the aboveground parts of the shallow-rooted grasses quickly dry out and die, the more deeply rooted trees can tap moisture lying further beneath the surface longer into the dry season. Grasses grow rapidly when moisture is available but die back when it is not, surviving long dry periods as dormant buds close to the soil

surface. The sandy soils, which supply abundant moisture during rainy periods but which dry out almost completely in the absence of rain, favor the grassy component of savannas. Trees, on the other hand, require water in at least small amounts at all seasons even if they drop their leaves; deep soil layers supply that need. Trees in savannas are favored by stony soils, which allow deep penetration by roots but which are less favorable to grasses. Nevertheless, especially toward the end of the dry season, many trees may lose their leaves to reduce transpirational loss of water, even though the leafless branches of some species carry open flowers. Soil, therefore, exerts some control over the nature of savanna vegetation, particularly in the drier parts of its distribution where sandy soils support grass-rich savanna with few trees and coarser, deeper soils support more tree-rich savanna with less grass.

### Effect of Anthropogenic Activity

Anthropogenic activities also disrupt fire and mammalian herbivory regimes, two of the key spatial processes maintaining open savanna ecosystems (Sankaran et al. 2005). In particular, changes in land management, commercial agriculture, and fragmentation by road networks alter the size, season, frequency, and intensity of fires, thereby altering natural fire regimes. The tree component of savannas generally becomes more important as rainfall increases, but other factors such as topography, soil, and grazing intensity all exert influences in complex and variable ways. Because grazing and fire are strongly affected by human activities and have been for thousands of years, humans continue to have a controlling influence on the nature, dynamics, development, structure, and distribution of savannas in many parts of their global range. The effect is especially pronounced when economic development and increased population densities cause cropland expansion (Andela et al. 2017). Indeed, much of the 25% decline in global fire can be attributed to increasing human influence in savannas. People have similarly impacted herbivory regimes with a continent-wide switch occurring across Africa from free-roaming

native herbivores to largely sedentary grazing livestock. These changes in herbivory regimes are further worsening by the continent-wide poaching (illegal hunting) of iconic African megaherbivores, like elephant and rhinoceros. The culling of wild mammals to prevent disease transfer to livestock has also drastically reduced population sizes, while fences and roads hinder migration and restrict range sizes. Smaller and more fragmented populations, in turn, diminish the ecosystem-engineering effects of megaherbivores on vegetation openness and nutrient distribution. Such engineering has likely influenced savanna structure and function since the Miocene (Charles-Dominique et al. 2016). Savannas are also affected by the overuse of woody plants for fuel. Together with grazing and cultivation, this depletes both the grassy and woody components of the vegetative cover. Often a subsequent acceleration of soil erosion occurs. Such processes are associated, in densely settled savanna areas such as Africa north of the equator, with the type of land degradation called desertification. Human impacts on one or more of the determinants of savanna structure and function. Clearly increased knowledge of their interactions will provide improved understanding of savanna processes and enable better management in a rapidly changing world. Savannas may be ideal ecosystems for agroforestry applications, rather than traditional cropping systems. Small shifts in fire regime may dramatically increase productivity; thus savanna systems could be used for carbon sequestration and greenhouse gas mitigation schemes, providing alternative livelihoods and aiding in the maintenance of biodiversity. Anthropogenic activity impacts the determinants of savanna structure and function. Increased knowledge of their interactions will provide improved understanding of savanna processes and enable better management in a rapidly changing world.

## Conclusion and Future Prospective

The impact of ecosystem services provided by savanna on human population is large, since one-fifth of the world population depends

on it. Anthropogenic activity impacts the determinants of savanna structure and function. Currently, savannas are undergoing rapid changes at the continental scale but unlike in forested biomes. The ongoing woody plant encroachment in savannas is detrimental to the ecosystem services provided to local people. Efforts to avert a crisis in savannas are impeded by inadequate understanding of the ecological mechanisms, driving observed changes, and of the diversity among savanna types in their resistance and resilience to change. These knowledge gaps hamper the development of sound management strategies at the local and regional scales. It is clear that increased knowledge of savanna processes and factor regulating it enables better management in a rapidly changing world. Savannas may be ideal ecosystems for agroforestry applications, rather than traditional cropping systems. Small shifts in fire regime may dramatically increase productivity; thus savanna systems could be used for carbon sequestration and greenhouse gas mitigation schemes, providing alternative livelihoods and aiding in the maintenance of biodiversity.

## Savings

Gabrielle Weidemann

School of Social Sciences and Psychology,  
Western Sydney University, Penrith, NSW,  
Australia

## Definition

Savings are the proactive influence of prior learning on later learning or behavior even when the originally learned behavior appears to have been eliminated.

## Introduction

In Pavlovian conditioning, the pairing of a neutral conditioned stimulus (CS: such as a tone) with an unconditioned stimulus (US: such as a puff of air to the eye) results in the acquisition of a conditioned response (CR: blink response to the tone). Following acquisition of the CR, presentations of

the CS alone result in the progressive elimination of the CR, known as extinction. In operant conditioning, following a response with reinforcement increases the frequency of the reinforced response which extinguishes when reinforcement is omitted. Superficially, the elimination of the CR in Pavlovian conditioning and the response in operant conditioning appears to be the reversal of the original learning. However, even after complete elimination of the CR or response, a substantial residual of the original learning is saved and, as will be detailed below, can be recovered in a variety of ways. That is, there are savings of the original learning which can be evidenced by the recovery of the CR or response and which proactively interfere with later learning even when the originally learned behavior has been abolished.

### **Spontaneous Recovery, Renewal, and Reinstatement**

Following the extinction of a CR in classical and a response in operant conditioning, the CR and response can spontaneously reappear, following a period without exposure to the cues, when the CS or antecedent cues are reintroduced (Pavlov 1927, p.58; Skinner 1938, p.78). This spontaneous recovery is transient and responding quickly disappears unless the CS is followed by the US or the operant response is reinforced. Responding is also renewed when the CS or antecedent cues are presented in a context other than the context in which extinction occurred and is strongest when returned to the context in which conditioning occurred (Bouton and Ricker 1994; Bouton et al. 2011). Also if the reinforcer is delivered independently of the response or the US is delivered independently of the CS then responding can be reinstated (Rescorla and Skucy 1969; Rescorla and Heth 1975). Spontaneous recovery, renewal, and reinstatement all indicate that the original learning remains in long-term memory following extinction and can re-emerge in performance of the original CR or response.

### **Rapid Reacquisition, Learning to Learn and Concurrent Recovery**

Additional to the re-emergence of the CR or response, savings can also be demonstrated in altered learning curves following the acquisition and extinction of Pavlovian and operant conditioning. In Pavlovian conditioning, spontaneous recovery and reinstatement can largely be abolished by conducting extinction across numerous days with delays between extinction sessions and by presenting the US during extinction but explicitly unpaired from the CS (Napier et al. 1992). Following this type of extinction procedure when the CS and US are paired again in reacquisition, reacquisition is much faster and shows a much steeper learning curve than either original learning in the same participants or compared to a control group that have received an equivalent amount of exposure to the learning context in the absence of the CS and US (Napier et al. 1992; Weidemann and Kehoe 2003). This faster rate of learning also transfers to a new stimulus, from a different sensory modality to the originally trained and extinguished CS, when it is paired with the same US (Kehoe et al. 1995; Weidemann and Kehoe 2003). This form of transfer has been labeled learning to learn, general transfer and nonspecific transfer. The training of the new stimulus also results in concurrent recovery of the original trained and extinguished CS without any additional pairings of the CS with the US. The amount of extinction training influences the magnitude of rapid reacquisition and learning to learn but has no effect on the degree of concurrent recovery (Weidemann and Kehoe 2003).

### **Theories of Savings**

Evidence for savings suggests that extinction does not eliminate the original learning but either results in new learning which retroactively interferes with the original learning to silence responding (Bouton and Ricker 1994; Bouton et al. 2011) or results in diminution of the original

learning which silences responding while some portion of the original learning remains protected (Napier et al. 1992; Weidemann and Kehoe 2003). Inhibitory theories of extinction and savings can successfully explain spontaneous recovery, renewal, reinstatement, and rapid reacquisition but have a great deal of difficulty explaining learning to learn and some aspects of concurrent recovery. Whereas, Kehoe's (1988) connectionist model of learning and extinction which incorporates a "hidden" unit layer which is common to all CSs paired with the same US and includes an attenuation and protection mechanism can explain rapid reacquisition and learning to learn but cannot explain spontaneous recovery, renewal, reinstatement, and concurrent recovery without some additional mechanisms (Weidemann and Kehoe 2003). A model which combines both layered connectionist architecture with inhibitory connections that are gated by features of the extinction context is able to explain most savings phenomena (Weidemann and Kehoe 2003).

### Implications of Savings for Therapeutic Procedures

Practically, extinction is the foundation of most exposure centered therapies for anxiety and addiction. Such therapies are highly effective, but, like laboratory based extinction, savings are commonly seen in the high rates of relapse. Hence understanding savings after extinction has widespread significance for improving the efficacy of clinical treatments for both anxiety and addiction. Both preclinical and clinical research on anxiety has shown evidence of savings following exposure based interventions and treatment. Current research is examining ways to strengthen the extinction memory and weakening the original conditioning memory in order to reduce savings (Vervliet et al. 2013).

### Conclusion

Evidence for savings following the acquisition and extinction of Pavlovian and operant

conditioning is seen in the form of the re-emergence of the CR or response such as during spontaneous recovery, renewal, reinstatement, and concurrent recovery. Alterations to the learning curve of Pavlovian and operant conditioning, as shown in rapid reacquisition and learning to learn, also indicate that there are savings of the original learning. No single theory of extinction learning is able to explain all of the different savings phenomena but a hybrid model that includes the formation of inhibitory connections during extinction that are gated by the extinction context and other forms of protection of the original learning can explain most savings phenomena. Therapeutic interventions that include exposure to either a source of anxiety or cues and situations that elicit craving can benefit from understanding savings phenomena to understand sources of relapse and to maintain and extend therapeutic outcomes in the client's ordinary environment.

## Scala Naturae

Lori Marino  
The Kimmela Center for Animal Advocacy,  
Kanab, UT, USA

## Synonyms

Evolutionary ladder; Great chain of being; Ladder of being; Phyletic scale

## Definition

A view of life from ancient Greece placing different kinds of natural objects on ascending levels of a fixed hierarchy with inanimate objects, that is, rocks, on the bottom and humans at the top level.

## Introduction

### History

The *Scala Naturae*, also known as the *Great Chain of Being*, is a model or view of life

formalized in ancient Greece first by Plato and then Aristotle (1910, 1912, for translations; Lovejoy 2011) and maintaining prevalence into modern times. It orders nature on a hierarchical scale of complexity, “advancement,” and value starting with inanimate objects, for example, rocks, on the bottom and ascending to “simpler” life forms, for example, plants, then invertebrates, and “up” to mammals, then primates, then humans. In versions of the *Scala Naturae* adopted in Medieval times, supernatural beings, for example, angels, occupy levels just above humans, with god at the peak.

According to Aristotle, the “principle of form” is more “advanced” in organisms higher on the scale than those lower. Describing the life forms as one moves up the *Scala Naturae*, Aristotle stated that “one after another shows more possession of life and movement.” The levels on the scale are static classes which, while linked, are fixed for eternity. Therefore, the *Scala Naturae* engendered a world view that, within a Medieval European religious context, saw god as perfect and all other creatures, including humans, as progressively less perfect semblances of god. Humans, however, occupied a special status in the hierarchy as the most “advanced” species and therefore closer to god than any others. Even a secular adoption of the *Scala Naturae*, however, views humans as “higher” than other animals, whose positions on the scale are determined by resemblance, not to god, but to humans.

Needless to say, the *Scala Naturae* is not supported by modern empirical evidence. Yet, it has held sway over scientific thinking for thousands of years. It was championed by Thomas Aquinas, who saw the levels as reflections of “divine order,” attaching great religious and value-laden significance to each. In the thirteenth and fourteenth centuries it found expression in the writings of such thinkers as St. Albertus Magnus and the medieval schoolman Nicholas of Cusa.

The *Scala Naturae* represents an idiosyncratic blend of two seemingly incompatible ideas: one that all organisms on the ascending levels are connected and, at the same time, remain fixed in their positions as distinct “kinds.” For instance, Leibniz (1646–1716) promoted the notion of

connection across levels which formed a single chain in his *Law of Continuity* based on the *Scala Naturae* all the while upholding the categorical distinctions across organisms.

Despite the more sophisticated later classification schemes of Linnaeus and Cuvier (<http://www.macroevolution.net/scala-naturae.html>), *Scala Naturae* thinking remained entrenched in “tree of life” depictions of nature. The idea of branching lineages of organisms was laid upon an overall view of “lower” to “higher” branches. Just before the emergence of Charles Darwin’s theory of natural selection, Jean Lamarck put forth the idea that nature represented progressive levels of “perfection” in nervous system organization and that as one moves up the hierarchy new psychological capacities emerge as nervous systems become more “perfect.” Although Lamarck may be best known for his abandoned theory of “inheritance of acquired traits,” his *Scala Naturae* notions about the brain and intelligence remain influential in modern thinking. Charles Darwin brought temporality and dynamism to our view of life but despite his revolutionary work *Scala Naturae* was not completely abandoned so much as superimposed upon his ideas.

In post-Darwinian times the *Scala Naturae* found new life in notions of phylogeny and teleology. Implicit in the *Scala Naturae* are teleological notions, that is, that there is a progression in cosmic and biological evolution toward better or more advanced organisms. This idea, or, rather, misconception, of evolution remains a “thorn in the side” of Darwinian theorists to this day. The modern “phyletic scale,” which reflects evolutionary relationships among species, is still a hierarchical scheme that promotes the idea that “higher” organisms are more “evolutionarily developed” than “lower” organisms. And while the phyletic or phylogenetic scale is based upon comparisons across current species, it is often interpreted as a linear scale of progression. For example, a linear scale would classify modern teleost fish “below” modern mammals despite the fact that modern fish and modern mammals do not have an ancestor-descendent relationship.

By the mid-to-late twentieth century scientists possessed a sophisticated understanding of

evolution and molecular genetics. Evolution came to be known as a change in gene (allele) frequencies over generations. Yet the notion of the phyletic scale continued to have a profound influence in many scientific fields and, in particular, those fields, like comparative psychology, that are focused explicitly on describing and explicating similarities and differences across species. Influential psychologist Harry Harlow wrote in 1958:

[S]imple as well as complex learning problems might be arranged into an orderly classification in terms of difficulty, and that the capabilities of animals on these tasks would correspond roughly to their positions on the phylogenetic scale. (p. 283)

As late as the 1970s the *Scala Naturae* was re-energized by the wildly popular book and television series *The Ascent of Man* by Bronowski (1974). In addition to the main title, his chapter titles, such as “Lower Than Angels” and “Ladder of Creation,” were clear affirmations of *Scala Naturae* thinking. The great poet Ralph Waldo Emerson wrote (<https://quotes.yourdictionary.com/author/ralph-waldo-emerson/49009>):

Striving to be man, the worm  
Mounts through all the spires of form.

Although this was written in the nineteenth century it very much reflects a current perspective on life originating in the *Scala Naturae*. “Lower” forms of life strive to gain ascendancy up nature’s ladder to reach the pinnacle of nature’s creation – humanity. Other animals are viewed as simpler and lesser versions of life than humans.

In the twenty-first century our understanding of the nature of life and its evolution completely rejects the validity of the *Scala Naturae*. And, indeed, it would be rare to find explicit advocacy for the *Scala Naturae* or Great Chain of Being sensu stricto in today’s world. Nevertheless, implicit notions connected to *Scala Naturae* remain firmly ensconced in both our public discourse and scientific language and thinking. It influences not only what kinds of questions are asked in science but how data are interpreted and explained. And this ancient model continues to have a profound influence on how we relate to and treat other animals.

## Impact and Implications in the Twenty-First Century

### Scientific Thinking

A cursory review of modern college-level textbooks, lesson plans, presentations, and scientific articles and webinars reveals that *Scala Naturae* thinking still strongly shapes our views and our language in the twenty-first century. One finds, in these sources, “scientific” phrases such as “lower versus higher animals,” “advanced versus primitive,” “subhuman,” “humans and animals,” and depictions of humans at the pinnacle of evolution above other modern species (Nee 2005), to name a few. All are evidence that, despite our scientific knowledge, we retain the ancient perspectives of linear and hierarchical thinking and assumptions about evolutionary “progress.” For instance, as recently as 2004, Lenton et al. described life through the ages with a ladder whose rungs “progress” from microbes to plants and, at the top, megafauna (i.e., large animals).

In the area of comparative psychology and other related scientific disciplines that involve comparisons across species the *Scala Naturae* shapes the directionality of scientific inquiry (Marino 2003). That is, most of comparative psychology is an exercise in identifying capacities that humans possess and a search for those same abilities in other species. Examples include the study of language, arithmetic ability, tool making and use, mirror self-recognition, and numerous other forms of cognition. Less often do we change the direction of inquiry, asking whether humans possess a characteristic known to exist in other animals. One might argue that it is more difficult to probe the existence of a cognitive or mental trait in another species that is absent in our species. However, the vast majority of questions about cognition, intelligence, communication in other species defaults to an exercise in determining “how low can you go” on the phyletic scale and still find that human characteristic. The influence of *Scala Naturae* thinking does not end there, however.

A longstanding stricture in science is the principle of parsimony (also known as Ockam’s Razor), that is, the requirement to give the

simplest explanation possible that explains the greatest number of observations. In the study of animal behavior and comparative psychology, neuroscience, and other related fields, it takes the form of Morgan’s Canon, which says that no activity or ability found in nonhumans should be interpreted in terms of higher psychological processes if it can be fairly interpreted in terms of processes or mechanisms that are lower in the scale of psychological evolution and development. While rules of parsimony are important guidelines in science the very definition of Morgan’s Canon presupposes a *Scala Naturae*-based view of life. It imposes a unidirectional restriction on scientific explanations that assumes other species are not as “advanced” as humans. And while we may assert that modern scientific thinking is free of these kinds of ancient biases, the very language used to define Morgan’s Canon belies this claim. As such, *Scala Naturae* thinking often pushes scientific explanation away from parsimony. An increasing number of cognitive abilities previously thought to be unique to humans are found in species distantly related to our species, that is, cephalopods, insects, fish. These include observational learning, numerosity, various short-term and long-term memory capacities, reasoning, and problem solving. Some of these capacities may only appear to be similar to those in humans but are based on different neurocognitive mechanisms. Yet, a summary application of Morgan’s Canon without considering all possibilities can lead away from parsimony and imposes the equally unwieldy formation of multiple explanations for the same phenomenon – a “complex” one for humans and “simpler” ones for members of other species. In response to this tendency toward linear hierarchical thinking, many contemporary scientists and philosophers have pointed out that the most parsimonious explanation can be one that recognizes continuity and functional convergence across humans and nonhumans.

### Human-Nonhuman Relationships

In addition to how we reason about scientific findings across species, *Scala Naturae* has had longstanding relevance to how humans treat other animals, resulting in global animal

exploitation, abuse, and extinction. *Scala Naturae* thinking has its origins in views that place different beings, including demographically different human beings, on different levels of the hierarchy with the implicit notion that as one goes “down” the hierarchy the value of those lives decreases. The viewing of humans as superior to all other life on earth is tantamount to speciesism, that is, viewing other animals’ lives as of lesser value and import than our own. Speciesism, and thus *Scala Naturae* thinking, is the core justification for vivisection and invasive research, factory farming, poaching, sport hunting, religious sacrifice, fur-wearing, confinement for entertainment, and other forms of aggression visited upon other animals by humans.

Even within the domain of animal welfare, *Scala Naturae* thinking allows for gerrymandered proscriptions about how to treat other animals in such formalized schemes as Utilitarian philosophies and the 3R’s. For instance, Russell and Burch’s (1959) 3R’s (Replacement, Reduction, and Refinement) are meant to guide research practice so as to mitigate as much suffering as possible. The principle of Replacement (replacing one species with another or, ideally, with non-animal methods) is often invoked to conduct invasive research on species “lower” on the evolutionary scale than others. Replacement would proscribe replacing dogs with mice and mice with frogs, for instance, working “down” the scale of presumed ability to suffer. This is similar to notions of eating “down” the food chain. But these principles are based more on presumed attributes of various species than evidence and are, in the end, merely reflections of our own longstanding biases.

## Conclusion

It is not possible, at this time in history, to determine whether the *Scala Naturae* is an expression of our species’ innate bias against other animals or whether it has been employed through the ages as a convenient proscription for mistreatment of other animals. Although both are likely to be the case, it is inarguable that these ancient views

continue to fuel some of the worst forms of violence against other animals throughout history to this day.

## Synonyms

[Territorial marking](#)

## Definition

Scent marking is a form of olfactory communication used by an animal that deposits its odor in specific places to transmit a signal to other animal.

Scent marking is mainly defined as a behavior displayed to mark territory ownership (Gosling 1982). However, nonterritorial species can also scent mark to communicate with conspecifics. So not all marking is territorial, and the meaning of the scent can vary according with the species, its social system, and ecological factors.

Because the scent remains in the environment for some time, it represents a way of olfactory communication and allows the owner to be identified by a rival even in its absence, reducing the costs of physical conflicts (Gosling 1982). The

scent may signal a threat and a fitness cost to the receiver that must evaluate the risk of being detected by the signaler, accounting for its competitive ability and the value of the marked resource to both individuals (Gosling and Roberts 2001). Therefore, the responses of competitors to scent marks are variable.

In intraspecific communication, scent marking can function for individual or group recognition, age and social status recognition, site familiarity, as sex attractant or stimulant, and even for intrasexual competition (Johnson 1973; Müller and Manser 2008). With interspecific communication, scents can be used to recognize a species, which can represent a prey or a predator, or even to signal warning and defense (Johnson 1973).

Because the scent remains in the environment, other individuals can also detect the signal and take advantage on it, which is called eavesdropping (Gosling and Roberts 2001). Scents used by males to chase rivals from an area, for example, can attract potential mates or even predators.

## Behavior

Scent marks can be eliminated by urination, defecation, or by the secretion of scent glands, which can be located in different parts of the body. Therefore, it is important to distinguish scent marking behavior from the elimination of urine and feces just for excretory finality. During the scent marking behavior, the individual leaves its odor by distinct movements at selected sites that are visited repeatedly. In some species, such as Ethiopian wolves (*Canis simensis*, Sillero-Zubiri and Macdonald 1998) and giant otters (*Pteronura brasiliensis*, Leuchtenberger and Mourao 2009), individuals may use specific postures during scent marking behavior. Ethiopian wolves scent mark raising a hind leg and by scratching the ground when urinating a scent post (Sillero-Zubiri and Macdonald 1998). Giant otters scent mark rubbing their legs on the ground and the front legs on the vegetation, spreading the secretions that are left on communal latrines or at campsites along the banks (Leuchtenberger and Mourao 2009).

The posture used during scent marking and also the frequency that an animal scent marks are commonly related with its sex and dominance rank (Leuchtenberger and Mourao 2009; Müller and Manser 2008; Sillero-Zubiri and Macdonald 1998). Dominant males tend to mark more often, and it is also common that the dominant overmark the scent of other members of its group (Leuchtenberger and Mourao 2009; Sillero-Zubiri and Macdonald 1998). Overmarking may be a strategy of reproductive suppression, especially when the dominant individual has reproductive priority within the group (Palagi et al. 2004).

Some species may also associate other marking behaviors to the scent marking ritual, as for example, giant otters rub their fore paws on the vegetation soon after they emerge from the water (Leuchtenberger and Mourao 2009). Associate-behaviors may produce a visual signal that reinforces the detectability of scent marks enlarging the distance that these marks can be found by receivers (Gosling and Roberts 2001).

Once the receiver has matched the scent, the response can vary, according with the function of the scent, the identity of the owner, the competition ability of the receiver, and the behavioral context. Because scents can transmit the identity of the owner, receivers can memorize the smell and react to a known scent differently than to a stranger one. Some hypotheses, as the dear enemy effect and the familiarity hypothesis, try to explain the reaction of animals to known signs. The dear enemy effect, for example, suggests that territorial animals respond more aggressively to neighbors than to strangers, which is common in social mammals that live under intense competition (Müller and Manser 2007).

## Location of Scent Marks

The range of scents is usually low, so the location of scent marks is relative to the level of threat from opponents (Gosling and Roberts 2001). Therefore, it is expected that the density of scent marks is higher at places that are more visited by rivals. Within a territory, usually scent marks are more concentrated at the boundaries, where

invasions are more eminent, or even toward the center (Gosling and Roberts 2001). But some species, like some primates and otters, deposit scents near food resources (Kruuk 1992; Miller et al. 2003). However, within the same species, the distribution of scents can change according to ecological constraints and population density.

## Composition

The chemical composition of scents is controlled by endogenous and exogenous factors, including hormones (Setchell et al. 2010), and is still unknown for many species. Scent marks contain a mixture of compounds, especially pheromones (a chemical compound that causes a behavioral and/or a physiological reaction on a receiver; Johnston 2003), and proteins, such as the major urinary proteins that stabilize the odors and maintain them for longer in the environment (Hurst et al. 1998). Because most of the chemical compounds of scents are genetically regulated, they can encode the identity of the sender.

Some species may present different scent glands that secrete different kind of secretions and scents, which may display different functions. In ring-tailed lemurs (*Lemur catta*), for example, both sexes present apocrine and sebaceous gland fields in their genital regions, while males have two additional glands at the labial and brachial regions (Scordato et al. 2007). Seasonal differences in the chemical composition of the secretion eliminated by labial, brachial, and scrotal glands suggest that scent marking functions for reproductive advertisement and intrasexual competition in this species. While the secretions of genital glands of both sexes present individual identity.

Although scents are used by other taxa, like insects and reptiles, those of mammals present a more complex range of components (Johnston 2003). The variety of components, their combination, and concentration lead to a range of complex olfactory signs that can be transmitted by scents. In Old World Monkeys (*Mandrillus sphinx*), for example, approximately 97 volatile components were identified in samples of scent-glands secretion, which may inform variable

(age, dominance rank in males) and fixed (sex, individual identity) cues of the signaler (Setchell et al. 2010). In Marmoset monkeys, females' (*Callithrix jacchus*) scent marks were composed by 162 identical components, but the concentration of highly volatile chemicals varied among individuals, suggesting that the quantity of these components allow individual identification (Smith et al. 2001).

## Conclusion

Scent marking is a way to communicate with conspecifics and also with other species. Scent marks are left at specific sites and transmit a signal even in the absence of the owner. Therefore, scent marks must be deposited at sites where they are easily found by intruders, maximizing the chance to be detected and reducing physical conflicts. The function of scent marking varies among and within species and may induce different reactions on the receivers. Scents are composed by a variety of chemicals that may transmit information of the sender as well as the age of the scent. The variety of messages that can be transmitted by these chemicals and their persistence in the environment make scent marking one of the most efficient and important communication system for many species.

## Synonyms

Adjunctive behavior; Collateral behavior; Superstitious behavior

## Definition

Schedule induction refers to the process of behavior being developed during inter-reinforcement intervals without explicit arranged contingency between its occurrence and the delivery of reinforcement but only by the repeated occurrence of intermittent scheduled reinforcers.

## Introduction

Schedule-induced behavior occurs at significant high rates as a result of exposure to intermittent reinforcement, having, in general, a post-reinforcement temporal location with an inverted U-shaped distribution along inter-reinforcement intervals. These behaviors were initially called adjunctive (Falk 1971) because it was thought that they occurred as adjuncts to target behaviors that were explicitly reinforced and that they had no apparent functionality on their own.

The first reported example of schedule-induced behavior was psychogenic polydipsia (i.e., excessive drinking), observed in laboratory rats when they were exposed to intermittent food reinforcement while being moderately hungry (but not thirsty), and did not have to drink in order to obtain the food reinforcer. The understanding of schedule-induced behavior as adjunctive behavior

has been challenged since its inception (Segal 1972), and recently two theoretical alternatives to account for their occurrence have been proposed (Baum 2012; Killeen and Pellón 2013; see below).

Staddon (1977) proposed a motivational explanation of induction based on competition for expression as a function of proximity to reinforcement: interim activities occur immediately after reinforcer delivery, while terminal activities occur before or just at the time of the presentation of the reinforcer. Schedule-induced drinking would be an example of interim activity, while magazine entering will be an example of a terminal one.

## Generality of Schedule Induction

Among the behaviors that have been described as schedule-induced are drinking (polydipsia), wheel running, pica, attack, air licking, wood chewing, escape, defecation, or smoking, and they have been observed in such diverse animal species as pigeons, rats, mice, hamsters, gerbils, pigs, monkeys, and humans.

When various schedule-induced behaviors are available simultaneously, they tend to organize within inter-reinforcement intervals in a sequential and orderly manner. For example, if rats can drink, run, and get into the food magazine, the typical distribution of behavior is as shown in Fig. 1, where drinking (licking) antecedes running (wheel turning), and they finalize by entering into the magazine.

Schedule-induced behavior has been observed to occur under a wide range of reinforcement schedules, including fixed interval, variable interval, fixed time, variable time, fixed ratio, differential reinforcement of low response rates, and in the extinction components of some multiple schedules. Different types of reinforcers/events have been used as inducers, mostly food, but also water, condensed milk, access to an activity wheel, brain electrical stimulation, and money. Details on how motivational variables related to reinforcement affect schedule induction will be described later.

**Schedule-Induced Behavior, Fig. 1** Mean ( $\pm$  SEM) of number of licks, wheel turns, and magazine entries recorded every second (bin) during inter-reinforcement intervals of a fixed time (FT) 60 s schedule. The FT 60 s schedule

delivered a single pellet of food every 1 min regardless of rats' behavior, i.e., animals did not have to lick, turn the wheel, or enter into the magazine for food pellets to be delivered. (Data taken from Gutiérrez-Ferre (2019))

### Motivational Variables that Influence Schedule-Induced Behavior

This is central in order to characterize the nature of schedule-induced behavior, and their study has been limited almost exclusively to schedule-induced drinking. The amount of licking and drinking depends on the level of hunger and is influenced by most variables related to food delivery, such as its frequency, magnitude, quality, or delay in its procurement, with more schedule-induced drinking as those parameters of food delivery are more favorable (Reid and Staddon 1990). However, schedule-induced drinking is not so dependent on characteristics of the liquid available, nor on the level of thirst. Even more, schedule-induced drinking is not observed when wet instead of dry food is used as reinforcer, and the use of intermittent water reinforcement does not induce food consumption. Water accessibility, however, has been shown to add value to the situation of food reinforcement, thus making it quite resistant to reduce or eliminate.

Figure 2 shows ideal inverted U-shaped or linear functions of schedule-induced drinking in terms of behavior being measured as units per reinforcer occurrence or per time elapsed and as a function of inter-reinforcement interval length. Behavior is controlled both by frequency of reinforcement (15–120 s) and by the magnitude of the reinforcer (1 versus 4 food pellets). Typically, in order to assess the effects of both rate and magnitude of reinforcement, it should be taken into

account that reinforcers also induce other patterns of behavior (see Fig. 1) that compete with each other for expression.

### Induction and Reinforcement as Behavioral Mechanisms

The study of schedule-induced behavior has led to the development of two theoretical accounts describing the mechanisms responsible for its acquisition and maintenance: reinforcement and induction. We will describe them as separate approaches even though there have been attempts for their integration (Ruiz et al. 2016).

Since the beginning of the study of schedule-induced behavior, some authors claimed that it was adventitiously reinforced. Although the proposal did not prosper until recent years, there are a few studies that evaluated the effect of consequences on schedule-induced behavior by, for example, introducing delays contingent to behavior emission. Killeen and Pellón (2013) extensively analyzed such literature and developed a model of competing traces to explain both schedule-induced and operant behavior. They proposed that different classes of behaviors have different temporal windows during which they can be reinforced; those temporal windows would be the exponential traces of proximity that determine the time that can elapse between the behavior and the delivery of the reinforcer for the behavior to be reinforced. More recently it was

### Schedule-Induced Behavior, Fig. 2

Ideal licks per reinforcer or licks per minute as a function of duration of the inter-reinforcement interval and of magnitude of reinforcer, expressing respectively bitonic or linear functions. (Data adapted from original transformations reported in Pellón (2012))

also proposed that behaviors are not just reinforced individually but that they collaborate and compete (Pellón and Killeen 2015).

On the other hand, Baum (2012) proposed a new paradigm in which he redefines the concept of operant behavior, replacing it with induction. He proposes that induction implies that some events in the environment increase the occurrence of a behavior, or the time spent doing that behavior, more closely related to the traditional definition of discriminative stimulus. Those events are called phylogenetically important events, and when they occur consistently with a behavior, a contingency in correlational terms is formed between them, resulting in the increase of that behavior when that event occurs. He also suggests that behaviors compete among them and distribute in a hierarchical way throughout the inter-reinforcement interval, similarly to what Staddon (1977) and Pellón and Killeen (2015) proposed.

### Implication of Neurobiological Circuits on Schedule Induction

Schedule induction has been related to two lines of neurobiological involvement: mesolimbic

dopaminergic pathways, focused on the motivational features of the incentive involved in the release of a reinforcer, and hypothalamic-pituitary-adrenal axis that proposes an adaptive function of schedule-induced behaviors as a response strategy to stressful situations. Several studies have evaluated the effects of pharmacological and lesion treatments/interventions on mesolimbic pathways and found that the amount of schedule-induced behavior was affected. On the other hand, animals that developed excessive-induced drinking showed decreased plasma levels of corticosterone. A further approach suggests that structural plasticity of cortical-striatal regions associated with goal-directed actions and habit formation could mediate the persistence and excessiveness developed during induction (Íbias et al. 2015).

Pharmacological studies have also evaluated if schedule-induced drinking can serve as an animal model of compulsivity and have suggested that induced behaviors may have common features with compulsive behavior in humans. This approach has tested the efficacy of drugs normally used to treat compulsive symptoms that involve the serotonergic system. Thereby, the use of antidepressants (i.e., selective serotonin reuptake

inhibitors and serotonin receptor agonists) decreases the amount/frequency of schedule-induced drinking (see Moreno and Flores 2012).

## Conclusion

Schedule-induced behavior refers to behavior that is induced by schedules of reinforcement in which there is not experimentally arranged contingency between occurrence of behavior and occurrence of reinforcer. This is why it was initially called adjunctive behavior, or even collateral behavior, but today schedule-induced behavior refers to the process by which schedules of reinforcement induce behavior that is evolutionary relevant to its obtention, thus setting the conditions for its subsequent strength by (correlation with) reinforcement.

## Schedules of Reinforcement

Adam Derenne  
University of North Dakota, Grand Forks,  
ND, USA

### Synonyms

[Instrumental conditioning](#); [Operant conditioning](#);  
[Reinforcement](#)

### Definition

A reinforcer is a stimulus that serves to maintain or increase the future probability of the behavior on which it is contingent. The term *schedule of reinforcement* denotes a particular method of reinforcing behavior. A variety of schedules of reinforcement exist, and each has unique effects on behavior.

### Introduction

In 1930, B. F. Skinner, then a graduate student at Harvard University, devised an experimental chamber to study conditioning in rats. Rats placed in this chamber learned to depress a lever which caused a food pellet to be delivered from an external magazine. The apparatus, known formerly as an operant chamber and colloquially as a Skinner box, helped launch a new era of behavioral research (Bjork 1993). An advantage of the method was that it permitted an extended sequence of behavior to be observed that was free of outside interference (Skinner termed this free-operant behavior). By comparison, most experiments on learning at the time consisted of a series of discrete trials, and the researcher was

required to reset conditions between each trial. Most importantly, Skinner found that the acquisition and subsequent patterning of the response to be orderly, which meant that the apparatus could be used to carry out a systematic examination of the factors controlling operant conditioning.

Initially, the effect of schedules of reinforcement did not concern Skinner. He first used an intermittent schedule of reinforcement as a way of conserving food pellets when his supply was low. He discovered not only that responding persisted but that the cumulative records obtained during partial reinforcement differed from those obtained under continuous reinforcement. Skinner soon realized that a variety of intermittent reinforcement schedules were possible and that each might shed light on response-reinforcement relations. Therefore, he began to make schedules of reinforcement a major focus of his research (Morgan 2010; Skinner 1956). The first major publication describing schedules of reinforcement was *The Behavior of Organisms* (1938), which was followed by Charles Ferster's and B. F. Skinner's seminal *Schedules of Reinforcement* (1957). Much of the work conducted by Skinner and colleagues involved defining various types of intermittent schedules of reinforcement, describing the performance each schedule characteristically produced, and manipulating different aspects of the task so as to reveal the key factors controlling performance. The discovery of the variables controlling schedule performance led eventually to the development of formal theories of schedule of reinforcement.

### Methods Used in Schedule Research

The operant chamber used in schedule research includes, at a minimum, a means by which multiple responses can be emitted, and multiple reinforcers obtained, without researcher assistance. Data collection commonly occurs under conditions that minimize external stimulation. For example, the chamber may be placed inside a sound-attenuating chest, and/or a white-noise generator may be used to help mask external sounds. To further create a high degree of

experimental control, the timing of feedings and the amount of food provided to subjects outside of the experiment are carefully controlled so as to keep constant the efficacy of the reinforcer. Each successive reinforcer obtained during data collection may reduce somewhat the efficacy of the next available reinforcer; therefore each reinforcer is typically small, and the number of reinforcers which subjects can obtain during a session is limited.

In Skinner's original research, the sound made by the mechanical operation of the pellet dispenser signaled to subjects that reinforcement was being delivered. Since then it has become commonplace to include lights and/or speakers in an operant chamber, so as to allow the researcher to signal in other ways the moment when a response produces reinforcement. Lights and tones are also commonly used to signal changes in the conditions of reinforcement (e.g., a transition from reinforcement to extinction or a transition from one schedule to another).

A majority of research on schedules of reinforcement has been conducted with pigeons and rats. For pigeons, it is typical for the response to be a key peck and the reinforcer to be brief access to a tray of birdseed. For rats, it is typical for the response to be a lever press and the reinforcer to be a food pellet. However, other responses and reinforcers have been used with rats and pigeons, and schedule research has also been conducted with humans and many other species of non-humans (e.g., fish, octopi, horses, and insects). Skinner (1956) famously presented nearly identical cumulative records obtained from several species and asked, "Pigeon, rat, monkey, which is which?" before suggesting "It doesn't matter" owing to the similar ways in which the environment acts on the behavior of different organisms. Since then a more nuanced view of the importance of general learning processes has been adopted by schedule researchers (e.g., Timberlake 2001).

The analysis of performances under schedules of reinforcement typically focuses on steady-state behavior, which emerges when subjects have fully adapted to the conditions of reinforcement. In

other words, a point is reached in subjects' training when additional observations will not reveal additional changes in behavior.

The results of early research on schedules of reinforcement were examined primarily through a visual analysis of the cumulative records created during data collection (cf. Lattal 2004). A cumulative record is a real-time, graphical representation of the responses and reinforcers generated during an experimental session. The records are made by a cumulative recorder, which includes a paper scroll that slowly unwinds with the passage of time, and a pen which moves each time a response is emitted and which also marks each time reinforcement is delivered. It was from cumulative records that Skinner was able to demonstrate that different response patterns typify each schedule of reinforcement, how those patterns first emerge in naïve subjects, and what transitional responding looks like when the contingencies are altered.

Cumulative records were long mainstays of research on schedules of reinforcement, but their use has become less common. One reason for the change is that researchers began using computers to precisely time and record each response emitted during the session, which allowed for a more precise and more molecular examination of schedule performances than permitted by cumulative records. Another reason is that behavior analysts have come to be less reliant on visual analyses of data; instead, group-statistical designs and inferential statistical tests are increasingly in use.

## Basic Types of Schedules

Because a schedule of reinforcement describes any rule by which reinforcers correspond to behavior, the number of potential schedules of reinforcement is very large. However, Skinner and colleagues devised a relatively restricted set of terminology for describing schedules as a way to simplify the discussion. The terminology they used also helped call attention to those variations in the environment that may be most helpful in understanding how reinforcement changes behavior.

## Continuous vs. Intermittent Reinforcement

A **continuous schedule of reinforcement** is one in which every response is followed by reinforcement; for this reason, it is arguably the simplest possible schedule. An **intermittent (or partial) schedule of reinforcement** is one in which only some responses are reinforced. Many different factors can make a schedule of reinforcement “intermittent,” and this gave rise to the distinctions among schedules of reinforcement described below.

Continuous schedules of reinforcement are known to create a high rate of responding and rapid behavioral change, and they are often used in at least the early stages of behavioral change interventions. (However, it is commonplace to later transition to an increasingly intermittent schedule so as to help shift control over the behavior from the intervention to other, naturally occurring reinforcement contingencies.) Intermittent schedules are also capable of producing a high rate of responding, but this often does not occur when the schedule is first introduced.

Extinction of responding is more rapid after reinforcement is withdrawn from subjects trained on a continuous basis than on an intermittent basis. The discovery that the persistence of responding during extinction should be inversely related to the frequency of reinforcement obtained during training seems counterintuitive. A common explanation for this finding is that it is easier for subjects to discriminate conditions of reinforcement from conditions of extinction when reinforcement is provided on a continuous schedule than when it is provided on an intermittent schedule (Mowrer and Jones 1945).

## The Four Basic Schedules of Reinforcement

B. F. Skinner made four intermittent schedules of reinforcement a particular focus of his research, and they are regarded today as the four basic schedules of reinforcement. They are the fixed-ratio (FR), the variable-ratio (VR), the fixed-interval (FI), and the variable-interval (VI) schedules of reinforcement.

A **fixed-ratio schedule of reinforcement** is one in which reinforcement is obtained by completing a certain number of responses, and the number of responses necessary to obtain a reinforcer is kept constant. The term “ratio” specifically refers to the ratio of responses to reinforcers. For example, under a FR 10 schedule of reinforcement, the ratio of responses to reinforcers would be 10:1, meaning that subjects would obtain reinforcement every time they emit 10 responses.

Performances under fixed-ratio schedules are characterized by what has been termed a “break-and-run” pattern of behavior. That is, subjects often do not initiate responding at the first opportunity; instead, there is first a period of time without responses that is then followed by a relatively rapid and sustained period of responding that culminates in the delivery of reinforcement. The initial period without responding has been referred to as a postreinforcement pause or as a preratio pause. The initial pause is not required by the contingencies and is of questionable benefit to subjects; therefore some researchers have suggested that pausing on fixed-ratio schedules of reinforcement may serve as an animal model of procrastination (Schlinger et al. 2008).

The duration of the pause is sensitive to the exact contingencies of reinforcement. Under relatively favorable conditions (e.g., the ratio is low), a pause before responding may be difficult to discern. However, when the ratio of responding to reinforcement is high, or the magnitude of the reinforcer is small, pauses may be of considerable duration. When subjects transition from a lower ratio to a higher ratio, or are maintained on a very high ratio of reinforcement, breaks in responding may repeatedly occur after responding on a given ratio has been initiated, creating a pattern known as “ratio strain.”

A **variable-ratio schedule of reinforcement** is one in which reinforcement is obtained by completing a certain number of responses, but the number of responses necessary to obtain reinforcement varies from reinforcer to reinforcer. The exact ratios used in each session are preplanned so that the researcher can control the mean response-reinforcement ratio (e.g., VR 10).

Performances under variable-ratio schedules are similar to those of fixed-ratio schedules in that a break-and-run response pattern may be observed. However, it's more frequently the case that the pause on a variable-ratio cumulative record is difficult to discern, and pause durations at a given variable ratio are usually shorter than those under an equivalent fixed ratio. Variable-ratio schedules are similar to fixed-ratio schedules in that pause durations increase when the ratio size is raised or the magnitude of the reinforcer is lowered. Additionally, however, variable-ratio pause durations are sensitive to the lowest ratio used during the session. For example, pause durations tend to be quite brief if sometimes a single response suffices to produce reinforcement (Blakely and Schlinger 1988).

A **fixed-interval schedule of reinforcement** is one in which reinforcement is obtained by emitting a response after a certain interval of time has elapsed. For example, under a FI 30 s schedule of reinforcement, a response emitted at least 30 s after the start of the interval would produce reinforcement; any earlier responses have no effect.

Performances under fixed-interval schedules are traditionally characterized as following a “scallop”-shaped pattern in that the rate of responding is low during the first part of the interval, but it begins to accelerate with the passage of time. However, scalloping is not evitable, and on many individual intervals, a break-and-run pattern appears instead (Dews 1978). Although fixed-ratio and fixed-interval schedules may share a tendency to create a break-and-run response pattern, in the former case the initial pause confers no obvious benefit, while in the latter case, the pause appears to reduce the number of unreinforced responses. Pause durations under fixed-interval schedules increase as a function of the interval duration. Pause durations are especially pronounced when the schedule is accompanied by a “clock” that signals the passage of time during the interval (Ferster and Skinner 1957).

One of the most striking findings from research with fixed-interval schedules is the propensity for subjects to repeatedly perform, in a stereotyped manner, some nonscheduled behavior during the interreinforcement interval. For example, if water

is made freely available during the session, then subjects may drink excessive amounts (polydipsia), or if another subject is present during the session, then it may be subjected to repeated attacks. Collectively, these corollaries of periodic reinforcement are known as adjunctive behavior (Falk 1971). Adjunctive behavior is more pronounced under fixed-interval schedules than on the other three basic schedules of reinforcement, but it has been observed to sometimes occur under fixed-ratio and variable-interval schedules.

A **variable-interval schedule of reinforcement** is one in which reinforcement is obtained by emitting a response after a certain interval of time has elapsed, but the period of time that must elapse before reinforcement can be obtained varies from interval to interval. As is the case with variable-ratio schedules, the duration of each of the intervals used during a session is preplanned so that the researcher can control the exact mean interval (e.g., VI 30 s).

Performances under variable-interval schedules are characterized by a relatively slow rate of responding that is maintained fairly evenly during the interval. The exact rate of responding is negatively correlated with the mean duration of the interval.

Fixed- and variable-interval schedules are sometimes combined with a “limited hold” requirement; under this arrangement, subjects have a limited period of time to emit a response after the interval ends before the opportunity to obtain reinforcement is lost. If the limited hold period ends without reinforcement, a new interval begins.

## Variables Affecting Schedule Performance

Performances under a given schedule of reinforcement are affected not only by the reinforcement contingency defined by the schedule but also by a host of other factors. Some of the variables affecting schedule performance pertain to manipulations that precede data collection on a given schedule. For example, when food is used as a reinforcer, performances vary with the level of

food deprivation used before data collection begins. Performances on one schedule of reinforcement may also depend on subjects' prior history with other schedules of reinforcement (e.g., Wanchisen et al. 1998). The performances of human participants are sensitive to how the schedule is described. For example, if participants are told that one schedule of reinforcement is in effect, when in actuality reinforcement is provided on a different basis, then the verbal description may gain ascendancy over the pattern of responding (Baron and Galizio 1983).

Researchers have considerable latitude over how a given schedule of reinforcement is carried out, and the specific parameters they set may have a considerable influence on behavior. For instance, performances vary with the specific ratio size or interval duration, with the quality and magnitude of the reinforcer, and with the amount of effort required to emit the response. Researchers may also choose to adjust the schedule by imposing a delay to reinforcement after the schedule is completed or by providing reinforcement on only a percentage of schedules. Performances are also affected by the addition of stimuli that accompany each response on a ratio schedule or that mark the passage of time on an interval schedule (Ferster and Skinner 1957).

Variations in the use of a given schedule of reinforcement allow researchers to more fully characterize how the schedule controls behavior, aids in the development of mathematical models of schedule performance, and better enables researchers to relate basic research to the variety of reinforcing contingencies that are present in the natural environment. However, some of the variables controlling schedule performances are difficult to deduce from manipulating schedule parameters and examining schedule performances. For example, fixed ratio and fixed interval produce different patterns of responding, but it is difficult to disentangle the roles that the contingency of reinforcement and the frequency of reinforcement have in creating this difference. Sometimes a more substantial departure from the usual methods is required; one solution is to use a **yoked schedule of reinforcement** in which performances on one schedule of reinforcement are

used to set conditions on a second schedule. In this instance, the interreinforcement interval obtained by one set of subjects on a fixed-ratio schedule may be used to select the duration of the fixed-interval schedule for a second set of subjects; in this way, the frequency of reinforcement is held constant, while the reinforcement contingency is allowed to vary (Killeen 1969).

## Other Simple Schedules of Reinforcement

The four simple schedules of reinforcement provide researchers with a mean of examining the effects of two basic distinctions involving the contingencies of reinforcement: whether reinforcement principally relates to work (ratio schedules) or time (interval schedules) and whether the exact work or time requirement is predictable (fixed schedules) or unpredictable (variable schedules). In addition to the four basic schedules of reinforcement, several other "simple" schedules of reinforcement may be recognized in that they feature a single rule that determines how reinforcement is obtained. (In other respects, such as how quickly steady-state behavior is obtained, "simple" schedules may differ considerably from each other.)

A variant to the ratio schedules described above is a **progressive-ratio schedule of reinforcement**. In this case, each ratio the subject completes is followed by a higher ratio. For example, each ratio might increase in steps of 5, beginning with a ratio of 5. Subjects therefore would be required to emit 5 responses for the first reinforcer, 10 responses for the second reinforcer, 15 responses for the third, etc. Progressive-ratio schedule sessions eventually end when the ratio becomes too high to support further responding; the final ratio subjects complete is known as the break point (or breaking point). Subjects are expected to be more persistent in responding (i.e., complete more ratios and reach a higher break point) when the reinforcer is particularly efficacious. For this reason, progressive-ratio schedules have been used widely in behavioral pharmacology as a way of measuring subjects'

motivation to obtain a particular drug, both under ordinary conditions of reinforcement and when a method of curbing the reinforcing properties of a drug is tested (Stafford et al. 1998). A related procedure is a **progressive-interval schedule of reinforcement**, in which the duration of the interval increases after every reinforcer.

Another ratio schedule is the **random-ratio schedule of reinforcement**. In this case, every response has a certain probability of reinforcement. For example, under a random-ratio 20 schedule, each response has a 5% probability of producing reinforcement). Like variable-ratio schedules, random-ratio schedules are both work-based and unpredictable. As a result, performances under the two schedules can be similar (Crossman et al. 1987). However, reinforcement under a random-ratio schedule is more truly unpredictable, and it has therefore been used repeatedly in research concerned with behavior under gambling-like conditions (e.g., Haw 2008). A related procedure is a **random-interval schedule of reinforcement**, in which the interval has a certain probability of ending every time a certain duration of time passes. For example, under a random-interval 4-min schedule, there may be after every 4 s a 1/60 probability that the interval will elapse, allowing a response to be reinforced (Millenson 1963).

A duration-based schedule of reinforcement is one in which reinforcement is based on the duration of a response (or responses) rather than on the number of responses. For example, rats might be required to hold down a lever for 10 s to obtain reinforcement. Reinforcement might be obtained after the subject emits several responses that have a collective duration of 10 s or after a single response that lasts 10 s. (In some versions of the procedure, responses shorter than the scheduled duration do not contribute to reinforcement and instead cause the criterion to reset.) In line with other basic schedules, the reinforcement contingency may involve a **fixed-duration schedule**, a **variable-duration schedule**, a **random-duration schedule**, or a **progressive-duration schedule** (cf. Valois et al. 2017).

Under a **fixed-time schedule of reinforcement**, reinforcement is delivered after a certain

period of time has elapsed. Unlike a fixed-interval schedule, subjects obtain reinforcement without emitting a response. In other words, reinforcement is not contingent on behavior. A **variable-time schedule of reinforcement** is similar, except in this case the period of time between reinforcement deliveries is not constant. B. F. Skinner (1948) demonstrated that subjects placed on a fixed-time schedule of reinforcement may begin to exhibit stereotyped response patterns during the interreinforcement interval that appear to be consistent with superstitious behavior in people; however, this interpretation has been challenged, and it has been suggested that the appearance of stereotyped response patterns under a fixed-time schedule is better understood from the standpoint of adjunctive behavior (cf. Staddon and Simmelhag 1971).

Certain patterns of behavior are associated with each schedule of reinforcement because those patterns tend to maximize reinforcement gain while minimizing the effort expended. However, subjects are still able to obtain reinforcement when a nonoptimal pattern of responding occurs, which allows performances under a given schedule to be variable. Two schedules make reinforcement directly dependent upon the rate of responding. Under a **differential reinforcement of low rate of responding (DRL) schedule**, the first response emitted after a certain period of time has elapsed is reinforced, but, unlike an interval schedule of reinforcement, responses emitted before the period has elapsed cause the timer to reset. In other words, DRL schedules require subjects to respond at a slow, steady rate. DRL schedules are most commonly used in applications designed to reduce, but not eliminate the frequency of a behavior. Alternatively, a **differential reinforcement of high rate of responding (DRH) schedule** may be used to create rapid responding. In this case, reinforcement depends on subjects emitting a response that satisfies a criterion for short interresponse times (e.g., to obtain reinforcement, one response must be emitted within .5 s of the previous response). In some cases, the criterion is extended to include the interresponse times for multiple responses (i.e., a

series of responses must be emitted within a specified period).

Other differential reinforcement schedules have been used most prominently in applied research (cf. Miltenberger 2015). In the case of a **differential reinforcement of alternative behavior (DRA) schedule**, a target behavior is placed on extinction, while an alternative, but normally less probable, response is made to produce reinforcement. In the case of a **differential reinforcement of other behavior (DRO) schedule**, the target behavior is again placed on extinction, and any other behavior produces reinforcement.

A **lag schedule of reinforcement** is used to promote response variability. In this case, the apparatus must permit more than one response to be made. Reinforcement depends on emitting a response, or in some cases, a response sequence, which differs from previous responses or response sequences (e.g., Lee et al. 2002).

## Combining Schedules of Reinforcement

Simple schedules of reinforcement can be regarded as representations of how basic contingencies of reinforcement alter behavior. Behavior analytic researchers have likened the contingencies present in simple schedules to “building blocks,” which, when combined with each other, give rise to the more complex contingencies found in conjunction with many natural forms of behavior (Zeiler 1984). As a step toward understanding how complex contingencies of reinforcement operate, researchers have examined the effects on behavior of combining two or more simple schedules of reinforcement in some manner. The different schedules might be presented to subjects at different times, or they might be presented simultaneously to subjects. The different schedules might operate independently of each other, or responses on one schedule may affect how reinforcement is obtained on the other. The different schedules may share a single response, or each might be associated with a different response. Finally, the different schedules might be accompanied by distinct discriminative stimuli, or variations in the contingencies might be unsignaled.

There is no single framework for classifying complex arrangements of schedules. Combinations of schedules are grouped below into three categories: cases in which simple schedules alternate, cases in which subjects can choose between simultaneously available schedules, and cases in which a compound schedule is created from two simple schedules.

## Alternating Simple Schedules

One way of combining schedules of reinforcement is to alternate which schedule of reinforcement is in effect throughout the session. Under a **mixed schedule of reinforcement**, two or more schedules of reinforcement are presented at different times, such that when one schedule of reinforcement is completed, another, different schedule of reinforcement may be introduced. For example, a session may be composed of a mixture of FR 20 and FR 40 schedules (i.e., a mixed FR 20 FR 40 schedule). This specific instance creates an intermediary between a FR and VR schedule of reinforcement in that the response requirement is not constant, but the variation is limited. A **multiple schedule of reinforcement** is similar to a mixed schedule, but in this case each of the two or more schedules used during the session is accompanied by a distinct stimulus. Performances under multiple schedules of reinforcement have shown that performances under one schedule of reinforcement depend on how relatively favorable the conditions of reinforcement are compared to another schedule of reinforcement. For example, pause durations are longer when a subject switches during a session from a low to high fixed ratio than when subjects complete two consecutive high fixed ratios (e.g., Baron and Herpolsheimer 1999).

A **tandem schedule of reinforcement** also involves an alternation of simple schedules during a session, but in this case two or more schedules are consistently presented in a regular sequence, and reinforcement is delivered only after the final schedule in the sequence is completed. For example, under a tandem FI 10 s, FI 30 s schedule of reinforcement, completion of the first (FI 10 s)

schedule causes the second (FI 30 s) schedule to begin, and completion of the second schedule leads to food reinforcement. Under tandem schedules of reinforcement, the change from one schedule of reinforcement to another is unsignaled. By comparison, under a **chained schedule of reinforcement**, each of the two or more schedules comprising the sequence is accompanied by a separate discriminative stimulus.

## Schedules of Reinforcement Used to Study Choice

A **concurrent schedule of reinforcement** is one in which two or more schedules of reinforcement are available simultaneously to subjects, and each schedule is associated with a different response. For example, a pigeon may be placed in an operant chamber that includes one key for which responses are reinforced according to a FR 10 schedule of reinforcement and another for which responses are reinforced according to a FI 30 s schedule. Subjects are not required to respond on both schedules, but there is an opportunity to maximize reinforcement by responding on the FR 10 schedule during the first part of the 30 s interval and then respond on the fixed-interval schedule when the interval nears completion.

Research with concurrent schedules of reinforcement most commonly employs concurrent VI VI schedules. Under this arrangement responding on either schedule may be reinforced at any time, but reinforcement is maximized by matching the choice for a given schedule to the relative frequency with which those responses are reinforced (this relation is formally encapsulated in the matching law; Herrnstein 1961). For example, under a concurrent VI 30 s VI 60 s schedule of reinforcement, subjects are able to obtain twice as many reinforcers from the VI 30 s schedule as they are from the VI 60 s schedule; therefore reinforcement is maximized by making twice as many VI 30 s schedule responses as VI 60 s schedule responses. Research with concurrent VI VI schedules has shown that humans and non-humans are adept at matching and that matching

is a characteristic of naturally occurring human behavior (e.g., Vollmer and Bourret 2000).

A **concurrent chains schedule of reinforcement** is one in which two chained schedules of reinforcement are available simultaneously to subjects. That is, a discriminative stimulus associated with the initial link in each chain is presented in conjunction with each simultaneously available response. Once subjects begin to respond on one chain, the other becomes inoperable, forcing the selected chained schedule to be completed. In this way, a concurrent chains schedule of reinforcement extends the study of choice to a more complex and temporally extended reinforcement contingency than (simple) concurrent schedules – one which includes both immediately present conditioned reinforcers and delayed primary reinforcers.

## Compound Schedules of Reinforcement

Compound schedules of reinforcement include two or more schedules that are simultaneously in operation and which share a single response.

In the case of a **conjoint (or superimposed) schedule of reinforcement**, subjects' responses simultaneously contribute to reinforcement on two separate schedules. For example, if a FR 5 schedule were to be superimposed on a FI 20 s schedule, then reinforcement would be obtained both for every fifth response and for every response emitted after 20 s have elapsed. If a fixed-time schedule were to be superimposed on a fixed-interval schedule, then subjects would have access to both response-dependent and response-independent reinforcers. A similar method is an **alternative schedule of reinforcement**. In this case, two or more schedules are again simultaneously in effect with a single response, but once reinforcement is obtained on one schedule, progress toward the other schedule is reset. Thus, under an alternative FR 5 FI 20 s schedule of reinforcement, subjects might obtain all reinforcement from the FR 5 schedule, all reinforcement from the FI 20 s schedule, or a mixture of reinforcement from the two schedules,

depending on how frequently each contingency is met.

Under a **conjunctive schedule of reinforcement**, two separate schedule requirements must be met before a response is reinforced. For example, when a conjunctive FR 5 FI 20 s schedule is in effect, reinforcement depends both on emitting five responses and on making a response after 20 s have elapsed. The two components to the conjunctive schedule may be satisfied in any order. An **interlocking schedule of reinforcement** combines a response-based criterion with a time-based criterion in a variable manner. Specifically, a certain number of responses must be emitted to obtain reinforcement, but the response requirement decreases with the passage of time. For example, under a conjunctive FR 10 FI 30 s schedule, subjects are required to emit 10 responses to obtain reinforcement at the beginning of the schedule, but as time passes, the number of responses required for reinforcement decreases until after 30 s have passed a single response suffices to produce reinforcement. How the response requirement changes over time can be varied. When the response requirement decreases slowly over time, performances on an interlocking schedule more closely resemble those typically obtained with a ratio schedule of reinforcement; when the response requirement decreases rapidly, performances more closely resemble those of an interval schedule.

Under a **higher-order (or second-order) schedule of reinforcement**, the completion of one schedule is treated as a response that is reinforced according to a second schedule. A stimulus change occurs each time the first schedule is completed, which serves as a conditioned reinforcer in that it marks progress toward completion of the second (higher-order) schedule. Primary reinforcement is obtained only after the second schedule is complete. For example, if the first schedule is FI 5 min, and the second schedule is FR 10, then subjects obtain reinforcement after every tenth FI 5 min schedule (Kelleher and Goldberg 1977). Higher-order schedules are designed to allow an extended observation of behavior to occur while subjects receive few reinforcements; they are used especially in the study

of behavioral pharmacology to help separate the reinforcing effects of drugs from other behavioral effects drugs may induce (cf. Di Ciano and Everitt 2005).

## Uses of Schedules of Reinforcement in Research

Schedules of reinforcement are an enduring and pervasive feature of research in the field of behavior analysis because schedule research serves a variety of purposes. Schedules of reinforcement shed light on how reinforcement affects learning and behavior and has provided researchers with a way to examine the effects of variations in reinforcement (e.g., positive reinforcement vs. negative reinforcement, primary reinforcement vs. conditioned reinforcement, immediate reinforcement vs. delayed reinforcement). Schedules of reinforcement are also essential tools in research on other behavioral phenomena, including extinction, stimulus generalization, contrast effects, verbal behavior and rule-governed learning, foraging, choice, gambling, addiction, self-control, animal cognition, behavioral economics, creativity, avoidance, and learned helplessness, to name some examples. Although a schedule of reinforcement is normally thought of as a rule that determines how responses are reinforced, schedules may also be used to help researchers conceptualize and describe the ways in which behavior leads to reinforcement in the natural environment. For example, the behavior of checking an inbox for new email messages may be likened to a variable-interval schedule of reinforcement, or complex behavior that involves a series of steps may be likened to a chained schedule of reinforcement.

Outside of basic research on learning, schedules of reinforcement are used in applied research on behavioral change interventions. Because schedules of reinforcement have predictable behavioral effects, schedule research provides guidance as to how a particular form of behavioral change can be accomplished. Other common uses of schedules of reinforcement in research include the use of schedules of reinforcement as

behavioral baselines for assessing drug effects in studies of behavioral pharmacology and the use of schedules of reinforcement to assess gene effects in studies of behavioral genetics.

## Scramble Competition Polygyny

Kela Powell and Kristine O. Evans  
Department of Wildlife, Fisheries and  
Aquaculture, Mississippi State University,  
Mississippi State, MS, USA

### Definitions

Scramble competition polygyny is a form of competition among males of species that occurs when resources or mates are not defensible (i.e., not able to be monopolized), thus individual males compete for access to females in a population.

### Introduction

Species must be flexible in their reproductive strategies to persist and maximize fitness contributions in resource-restricted environments. Thus, a wide variety of mating systems have evolved, including polygynous behavior where males obtain multiple female mates. When resources or female mates are not defensible, males of some species will compete for direct access to females in a form of scramble competition. When males compete for access to

multiple females, scramble competition polygyny occurs.

## Scramble Competition Polygyny Life History Strategy

Polygyny is a mating system in which a male will mate with multiple females to maximize his reproductive potential. Scramble competition polygyny is a variation of polygynous behavior that arises in environments where resources or mates are limited and/or distributed in a manner that prevents securing or defending a territory or individual female mates during the breeding period. Sexual selection in the form of mate choice is a component of this particular mating system, which includes a “scramble” among males to search for and gain access to female mates, and a preference by females for males with greater mate searching capacity.

Scramble competition can take many forms, including variation in home range size, short-term guarding of mates, as well as energetic expenditure as males move around to gain access to females. The wide variety of behaviors that can be characterized by scramble competition have therefore been the focus of several studies in an effort to understand behavioral mechanisms, as well as the net fitness outcomes in different species (Kappeler 1997). For example, male gray mouse lemurs (*Microcebus murinus*) have been shown to increase home range size over time during the mating season, indicating the occurrence of scramble competition as males search for available female mates (Radespiel 2000). Energetic costs of male North American red squirrels (*Tamiasciurus hudsonicus*) have also been shown to be very high as a result of scramble competition. Thus, food and resource availability during the breeding period may limit reproductive success in males of this species, if energetic demands cannot be met (Lane et al. 2010). However, these energetic demands were only shown to occur during circumstances of intensified investment in males and did not persist throughout the year. These particular studies assist researchers in understanding the complexity of how resource

availability can determine the effects of scramble competition polygyny.

Researchers have also assessed scramble competition polygynous mating systems in gopher tortoises (*Gopherus polyphemus*; Johnson et al. 2009), some amphibian and fish species (e.g., Miranda et al. 2008), fiddler crabs (*Uca paradossumieri*), and many mammals and insects (e.g., Dickinson 1992). In one study by Murai et al. (2002), researchers observed scramble competition polygynous behavior in fiddler crabs during the mating season. Upon finding an ovulating female, the male fiddler crab quickly mate with the female, then guard her for a period of time before departing in search of another female. In this case, the sequence of events that included searching, guarding, and searching again for a mate represents scramble competition, and males may fertilize multiple females during this time. Throughout the courtship period, the male crabs became quite aggressive toward other males. Females will lay a clutch of eggs inseminated by the guarding male but have also been shown to mate with multiple males – potentially reflecting an ambisexual polygamous mating strategy across both sexes in addition to scramble competition.

Some desert tarantula (*Aphonopelma spp.*) species also display discrete courtship strategies associated with scramble competition polygyny but limited instances of male-male aggression or mate guarding (Shillington and Verrell 1997). Courtship can occur in rapid succession in these tarantula species, with multiple males in a “scramble” to reproduce with as many receptive females as plausible. Sphecids wasps (*Palmodes praestans*) also show evidence of nonterritorial patrolling and scramble-competition to seek out isolated nests of females (Alcock and Kemp 2005). Thus, reproductive success in these invertebrate species depends wholly on the male’s ability to search for, locate, and reproduce with as many females as energetically possible.

## Conclusion

Many species engage in some form of competition to enable them to survive and reproduce, with the

intent of maximizing the passing of genes to their offspring. Scramble competition polygyny is studied in various animal populations to understand the interactions of how this mating system may maximize fitness in both males and females. For researchers, scramble competition polygyny is an important component of some species’ life history and can aid in understanding of the complexities of competition and resource availability.

## Scramble Defense Polygyny

Kristine O. Evans

Department of Wildlife, Fisheries and  
Aquaculture, Mississippi State University,  
Mississippi State, MS, USA

## Synonyms

Defense polygyny; Scramble competition polygyny; Scramble polygyny

## Definition

Polygyny is a mating strategy through which a single male secures or attempts to mate with more than one female during a breeding period to optimize reproductive success. Scramble polygyny is one tactic taken by males whereby an individual attempts to secure as many female mates in a given area at a given time through a competitive searching approach. Defense polygyny involves behaviors that attempt to control access to females or resources required by females through territoriality. Thus scramble defense polygyny, though ill-defined as a concept, may represent a combination of nondefense scramble behavior and defense behavior in males to obtain a maximum number of female mates.

## Introduction

Males and females of many species exhibit flexible mating strategies to optimize reproduction under a variety of conditions. These strategies taken together comprise a species' mating system. Polygyny occurs when a male of a species mates with multiple females during a breeding season. Polygyny is thought to be the most common mating strategy in mammals (Clutton-Brock 1989) but is prevalent in many other taxa as well. Within the scope of polygynous behavior, males may exhibit a suite of tactics to mate with as many females as biologically reasonable given availability of receptive females in the area. However, ability to mate with multiple females may be constrained by factors of resource availability, energy requirements, and competition with other males. The polygynous mating strategy is thus a trade-off among the benefits of securing multiple female mates with little to no parental care required vs. the costs of competition and defense. One strategy involves either direct defense of females by males or, more commonly, defense of resources required by females through territoriality to secure successful copulations with multiple mates – hence the term “defense polygyny.” On the contrary, scramble polygyny is a form of non-defense polygyny whereby males partake in competitive searching for a maximum of female mates. There is no definitive defense of resources or mates in scramble competition, and this reproductive success is determined by which male can cover the greatest area and has the greatest skill in locating receptive females prior to other males. Success, in the case of scramble competition, is directly related to movement and search behavior, as well as economics of energetics required to win access to females through exhaustive search efforts.

## Scramble Defense Strategy

Scramble defense polygyny is a largely ill-defined concept that likely reflects a flexible mating strategy where nondefense tactics, such as scramble competition behavior may be

combined with temporary defense tactics. The term “scramble defense polygyny” is rarely used and ambiguous, though mentioned in Lombardi (1998) where seemingly defined as synonymous with scramble competition polygyny. Thus, the term is in need of clarity in definition. The utility of this strategy, as defined here, is determined by the distribution of females, density of competing males, and plausibility of short-term defense tactics in an area during a given time. It is reasonable to assume that scramble defense polygyny will occur as a strategy when density of males, and thus competitors, is great enough that territorial or direct female defense is not economical. However, some level of defense, likely intermittent and sequential in nature, must take place as males temporarily defend females or territories to allow enough time for fertilization. Similar to Dobson’s (1984) “density-male hypothesis,” if male density is high in populations that are restricted in spatial distribution, nondefense polygynous behavior, plausibly scramble competition, will be the dominant strategy. When densities of males in this same population are relatively low, males will switch to defense polygyny and exhibit territorial behavior. Dobson tested this hypothesis in ground squirrel species and found it is not simply density of males dictating this behavior, but that female density and clumping (or dispersion) of female distributions and timing of receptivity also play an important role in mating tactics.

Male rodents, in particular, exhibit flexible mating strategies to secure female fertilization. This includes defense strategies as reviewed in Waterman (2007), including black-tailed prairie dog (*Cynomys ludovicianus*), yellow-bellied marmot (*Marmota flaviventris*), American porcupine (*Erethizon dorsatum*) several species of ground squirrel (*Spermophilus* spp.), and others. Some aspects of behavior in thirteen-lined ground squirrels (*ICTIDOMYS TRIDECIMLINEATUS*) have been linked to scramble defense polygyny whereby individuals will actively search for broadly distributed females and reproductive success is dependent on ability to access female mates,

which was influenced by spatial-memory of sites where female interaction had previously occurred (Schwagmeyer 1994).

## Conclusion

The optimum strategy for mating in most species is intricately tied to energetics and likelihood of reproductive success. Success in polygynous mating strategies is related to availability, distribution, and receptivity of females in a given area, as well as competition among other males for mates, and female or resource defense tactics. Scramble defense polygyny by definition should demonstrate elements of scramble, or competitive search behavior. However, it is unclear due to the mixed-use of the term in the literature whether it is synonymous with scramble competition, or a separate strategy that incorporates short-term or sequential defense tactics while engaging in competitive search behaviors. Scramble defense polygyny, as a discernable mating strategy, is in need of improved definition and differentiation from other strategies.

## Introduction

The expression “specific searching image,” usually shortened nowadays to “search image,” was popularized first by Jakob von Uexküll (1934) and later by Lukas Tinbergen (1960). It is typically used in the context of a predator deploying

selective attention for finding cryptic prey. “Searching” in front of “image” specifies that an individual is making a concentrated effort to detect and identify something in particular, and “effort” pertains to selective attention. Being a particularly demanding cognitive process, selective attention is subject to severe limitations (Dukas 2004), implying that selective attention will be deployed only after being primed in some fashion (Blough 1989) and also implying that, after priming, selective attention will be sustained for only a short time.

However, while “search image” may be a convenient, casual expression to use in the context of discussing selective attention, it has a history of being discussed in inconsistent and often confusing ways. Early on, Marian Dawkins (1971) suggested that the term had become too imprecise to be useful, but her advice went unheeded. The expression “search image” is still used and often it is still imprecise.

## von Uexküll and Tinbergen

In 1934, von Uexküll wrote of how, at dinner time, he was accustomed to finding a clay pitcher of water on the table in front of where he sat. However, when he went to pour himself a glass of water one day, he became flustered by not seeing the expected clay water pitcher. When he asked the butler where the water was, the butler confessed to breaking the clay pitcher, but pointed out that the water was there in plain sight where it should be, only now in a glass carafe. Reflecting on this experience, von Uexküll proposed that nonhuman animals use search images in ways that are similar to his water-pitcher anecdote. A core meaning that may have been behind his use of this expression is that “image” in “specific searching image” corresponds to what is now more often referred to as a “representation.” More specifically, this means that an individual has become selectively attentive to a stimulus corresponding to a particular representation.

With his search-image hypothesis, von Uexküll was being provocative because he appeared to be talking about animal cognition. In

his time, such talk would have been widely regarded as scientifically disreputable because, in those days, “animal cognition” was often automatically associated with the notion of animals having subjective experiences (Kennedy 1992). However, there is no obligation to take that step. It may be easy to imagine what it was like for von Uexküll in the water-pitcher story, and intuition derived from anecdotes can be useful as the rationale for hypotheses, but intuitions about subjective states are not themselves hypotheses that can explain anything.

It was primarily with Tinbergen (1960), rather than von Uexküll, that the expression “search image” became widely used in biology and especially in ecology (Bond 2007). Tinbergen’s field-based research, which took place in the Netherlands, began in 1946 and ended abruptly in 1955 with his untimely death at the age of 39 (Baerends and de Ruiter 1960). Five years later, his work was published posthumously (Tinbergen 1960) in a monograph that included his search-image hypothesis. Unlike von Uexküll, Tinbergen mobilized a massive amount of data as the rationale for his proposed hypothesis. These data came from meticulously recording the different types of insects that the birds he studied (tits) took back to their nests and fed to their chicks. He also estimated the relative abundance of the different types of insects in the field. Tinbergen’s data revealed that tits did not prey on the available salient insects in the environment at a rate corresponding to the relative abundance of the different prey. Instead, Tinbergen found a trend toward rarer prey being neglected and more common prey being over-selected.

On the basis of his field-sampling data, Tinbergen proposed that the birds in his field site were using specific searching images, and he also proposed that his birds, and predators in general, may use search images in a flexible manner. More specifically, Tinbergen proposed that a prey type more abundant at a given time becomes the predator’s search-image target and then, when this prey becomes less abundant, the predator switches to using a search image for targeting a different salient prey that has now become more abundant. This particular hypothesis has become especially

influential in ecology, where it is closely associated with a particular category of natural selection known as “negative frequency-dependent,” or “apostatic,” selection (i.e., owing to the predator, rare forms of the prey have greater fitness and more common forms have lesser fitness). Apostatic selection (rare-form advantage) is of particular interest because it may account for the maintenance of prey diversity and also explain the evolutionary origin of polymorphism within single populations of single prey species.

This is an impressive legacy, but some important distinctions need to be clear when discussing Tinbergen’s work. Tinbergen presented field-sampling data in support of a conclusion concerning negative frequency-dependent predation, and then he used this conclusion as the rationale for proposing a hypothesis, not a conclusion, that his birds were using specific searching images flexibly (i.e., he proposed, but did not demonstrate, search-image use combined with switching). Later, the distinction between negative frequency-dependent predation and search-image use was often overlooked. This is a nontrivial problem because search-image use is not the only viable explanation for the occurrence of negative frequency-dependent predation. Alternative explanations include reliance on an acquired preference (i.e., preference for familiar targets) and non-selective adjustment of searching effort (referred to as the “search-rate hypothesis” by Guilford and Dawkins 1987). Effects derived from search-image use and effects derived from other mechanisms can be distinguished from each other, but only with appropriately designed experiments (Zentall 2005).

### Experimental Evidence of Search-Image Use

When the goal is determining whether individuals are using specific searching images, experiments should include priming events followed by trials in which an individual’s capacity to detect and identify objects is tested (Kamil and Bond 2006; Langley 1996; Reid and Shettleworth 1992). The priming stimulus is often called a “cue” and the object to be identified during a trial is often called

a “target.” During experiments, it is important to vary the difficulty the subject will have (i.e., the required attentional effort) when attempting to detect and identify a target, with the expression “cryptic” being used when the target is more difficult to detect and identify and “conspicuous” being used when targets are easier to detect and identify. The rationale for the cryptic-conspicuous comparison is a prediction that the benefit the subject will derive from deploying selective attention will be especially pronounced when the target is cryptic (Dukas and Kamil 2000).

Some of the most elegant evidence of animals adopting specific searching images has come from experiments based on using photographic images of prey (Pietrewicz and Kamil 1979) and computer-generated digital (virtual) prey (Bond and Kamil 1999) as surrogates for living prey. As a major milestone, Bond and Kamil (2002) demonstrated experimentally that flexible search-image use by a predator can result in an initially monomorphic prey population becoming polymorphic. In these experiments, living predators (blue jays) searched for digital moths displayed on computer monitors and the prey populations evolved via a genetic algorithm. These were true evolutionary experiments happening in real time, not simulations.

## Learning to See

Tinbergen (1960) also found some especially evocative ways of characterizing what he meant by search-image use. For example, he called using a specific searching image “a highly selective sieving operation” (p. 332), which appears to be his way of acknowledging the role of selective attention (Broadbent 1958). He also proposed that, after discovering a particular type of prey, a predator can “learn to see” it. By “learn,” Tinbergen probably meant that a bird gradually assembles a template or prototype which is then deployed in the service of detecting and identifying a stimulus matching this prototype (Shettleworth 2010; Watanabe and Sasaki 2015).

Perhaps it is unsurprising that, after Tinbergen, it became conventional in search-image experiments to expose test subjects to a stimulus corresponding to a specific target not once but repeatedly. After all, this would appear to simulate the manner in which Tinbergen proposed that his birds gradually acquired representations (images) by learning. However, research using jumping spiders (family Salticidae), instead of birds, illustrates the importance of maintaining a sharp distinction between first demonstrating the use of search images by animals and then explaining the manner in which search images (representations) are acquired.

## Search-Image Use by Salticid Spiders

Being predators with exceptional proficiency at detecting and identifying prey by sight, salticids may be the spiders which most closely resemble birds, but with important practical differences. For example, ensuring that prior experience has been standardized tends to be a lot easier when salticids are used as experimental subjects. This is illustrated in experiments pertaining to search-image use by *Evarcha culicivora*, a salticid with an active innate preference for mosquitoes as prey. However, the details of these experiments (Cross and Jackson 2010a) differ strikingly from more familiar experiments on birds. Each test spider, for example, experienced only one exposure to a priming stimulus, and this single exposure was its only prior experience with this stimulus. Moreover, this single exposure was not accompanied by anything corresponding to conventional reinforcement.

The priming stimuli and the targets were lures made either from the preferred prey (mosquitoes) or from mates (opposite sex conspecific individuals). During the priming period, the test spider was inside a glass chamber from which it could see prey lures or mate lures (no lures were present during control trials). At the end of the priming period, the test spider was transferred to an arena where its task was to detect and identify a lure made from prey or a lure made from a mate, with

the lure being outside the transparent glass arena. This meant that, during experiments, *E. culicivora* could see, but not contact or smell, these priming stimuli and targets.

No priming effects were evident when the lures were conspicuous. However, when the lures were made “cryptic” by being covered with nylon netting and by adding distractors (cork discs) to the scene, more spiders found prey after being primed by seeing prey, and more spiders found mates after being primed by seeing mates.

### Using Specific Olfactory Searching Images

Tinbergen’s expression “learning to see,” along with “image” in “specific searching image,” may suggest that search-image use pertains solely to selective visual attention. However, this restriction is unwarranted because selective attention and representation are relevant irrespective of sensory modality (Spence and Driver 2004). For example, mammals (dogs and skunks) have been used in experimental studies aimed at detecting the use of olfactory search images (Gazit et al. 2005; Nams 1991, 1997), but, as no cryptic-conspicuous comparisons were included in these experiments, reliance on acquired preferences is a credible alternative explanation for the findings. Nams (1991) made the interesting suggestion that the cryptic-conspicuous distinction is clearly applicable only when the sensory modality is vision, but this is misleading because, in the context of selective-attention experiments, the cryptic-conspicuous distinction pertains to how attentionally challenging a task is to the animal irrespective of the sensory modality.

In an olfactory search-image study using *E. culicivora* (Cross and Jackson 2010b), target odor was made cryptic by using a masking odor from *Lantana camara*, a highly aromatic plant which *E. culicivora* is known to detect and respond to (Carvell et al. 2017). During priming, the test spider could smell, but not see or contact, mosquitoes or a mate (no odor source was

present in control trials). After priming, the test spider’s task was to find the source of the target odor (mosquito or mate), again with no opportunity to see or touch the odor source. Depending on the experiment, the target odor was either cryptic or conspicuous. Besides the presence of a masking odor in cryptic trials, the test spider had to pass through a “transition chamber” before it could get close to an odor source, the rationale being to make the source of the test odor even more difficult to find. In conspicuous trials, the transition chamber and masking odor were absent.

No priming effects were detected during conspicuous trials. However, in cryptic trials, more spiders found the source of mosquito odor after being primed by mosquito odor and more spiders found the source of mate odor after being primed by mate odor. The close similarity between these findings and the findings from the visual search-image study illustrates that the sensory modality is secondary: search images are fundamentally about selective attention.

### Trade-Offs

Tinbergen (1960) suggested that birds might make use of more than one search image at a time, but subsequent research has given very little support to this particular hypothesis. Instead, it is now widely accepted that, even for big animals such as birds and mammals, selective attention is subject to severe capacity limitations (Dukas 2004) and that these limitations will lead to impaired performance when an animal’s task is to find more than one kind of target in any given session (Langley 1996; Pietrewicz and Kamil 1979; Shettleworth 2010). These trade-off effects, in turn, are the basis for predictions which can be used for distinguishing between search-image use and either acquired preferences or nonselective increase in searching effort.

When considering these predictions, the distinction between congruent and incongruent priming is important. This is illustrated in the

search-image experiments using *E. culicivora* (Cross and Jackson 2010a, b). In these studies, the priming stimulus was either the same as the target during experimental trials (congruent) or different (incongruent), with no priming stimulus being used in control trials.

When targets were conspicuous during experimental trials, performance at detecting and identifying them was much the same regardless of whether there had been congruent, incongruent or no priming beforehand. This is contrary to what the acquired-preference hypothesis would predict: if the spiders were simply expressing a preference for familiar targets, then strong evidence of preference would be expected when the target is especially easy to detect and identify. On the other hand, when targets were cryptic, performance was better after congruent priming than after incongruent priming or after no priming (control), as predicted by the hypothesis that priming triggers selective attention to the primed-for target. Also, when targets were cryptic, performance after no priming was better than after incongruent priming: compared with performance after no priming, *E. culicivora* individuals that had been primed by seeing or smelling mosquitoes became less successful at detecting and identifying mates and individuals primed by seeing or smelling mates became less successful at detecting and identifying mosquitoes (Cross and Jackson 2010a, b). This combination of findings was expected on the basis of selective attention being accompanied by trade-off effects (also see Langley 1996) but not expected on the basis of effects from nonselective adjustment of searching effort (i.e., the “search-rate hypothesis”: Guilford and Dawkins 1987). When nonselective adjustment of searching effort is all that is occurring, the subject is predicted to detect and identify both target types at least as well as in control trials. Impaired performance in both of the two kinds of incongruent trials (mosquito as target after priming with mates and mate as target after priming with mosquitoes) is expected when selective attention is deployed and unexpected when only nonselective increase in attentional effort is deployed.

## Cross-modality Priming of Selective Attention

Cross-modality priming of selective attention occurs when a priming stimulus in one sensory modality prepares an individual to detect and identify a target stimulus in a different modality (Spence and Driver 2004). Although search-image use is most often discussed in the context of same-modality priming (e.g., visual stimuli priming selective attention to corresponding visual targets), it can also be considered in the context of cross-modality priming and this may be especially useful as a warning not to assume that search-image use must be tightly linked to perceptual learning.

When *E. culicivora* was used in same-modality (vision or olfaction) search-image studies (Cross and Jackson 2010a, b), the only reinforcement individual test spiders might have received was from a single instance of simply seeing or smelling a prey individual or a mate. One-trial perceptual learning in the absence of conventional reinforcement may be conceivable, but unlikely. However, even this remote possibility was ruled out in a study (Cross and Jackson 2009) in which there was no conventional reinforcement and yet cross-modality priming occurred in two directions (visual priming triggering olfactory search-image use and olfactory priming triggering visual search-image use).

The methods used in these cross-modality priming experiments had basic similarities to the methods used in same-modality priming experiments, including lures being either cryptic or conspicuous and including priming being either congruent or incongruent. The findings were also similar: seeing mosquitoes made test spiders more proficient at locating a source of cryptic mosquito odor and smelling mosquitoes made test spiders more proficient at locating cryptic mosquitoes by sight. However, in these cross-modality experiments, one-trial perceptual learning was irrelevant. The spiders had no experience with mosquitoes before being used in experiments and yet odor priming made test spiders more proficient at finding mosquitoes by sight and visual priming made test spiders more proficient at finding mosquitoes by olfaction.

## Conclusion

Tinbergen played a major role in generating interest in search-image use by animals, but it would be artificial and counterproductive to restrict discussing search images solely to the contexts of predators responding to prey, individuals relying on a single sensory modality (vision), or representations being acquired by perceptual learning. The expression “specific searching image” needs to be aligned clearly with selective attention and representation (Zentall 2005), with search-image use as a phenomenon being kept conceptually distinct from issues related to, but not defining, search-image use. Related issues include the manner in which the “image” (representation) is acquired, the consequences of trade-off effects and the role of search-image use in the evolutionary origin and maintenance of prey polymorphism. Of course, it might be argued that, for a mechanistic understanding of search-image use, the goal should be an understanding of underlying neural processes and that acquiring an understanding at a neural level will remove the need for talking about “specific searching image,” along with “representation,” “priming,” and “selective attention” (Anderson 2011; Mandler 2013); however, while striving for this ultimate goal, clear conceptual distinctions and consistent use of terms have an important role in indicating what needs to be explained.

## Definition

Strategies used by prey to defend them from predator when they are singled out by them.

## Introduction

For sustaining life, energy is necessary, and it is gained by eating other organisms, either wholly or partly. All organisms are a predator in a certain way and at the same time prey for other organisms. For example, if the lion is the predator for impala, then in certain cases, they become prey for hyenas as they are their natural enemies. So, predation acts as the selective force leading to coevolutionary arms race between them and prey and thus driving the ecology and evolution of

both of them (Abrams 2000; Wang et al. 2018). To avoid predation, prey organisms have evolved morphological, physiological, and behavioral adaptations.

Antipredator defense mechanism can be categorized into two types depending upon when they are used. These types are primary defense mechanism and secondary defense mechanism (Barnard 2004). Primary defense mechanisms are those which are used by organisms to avoid getting detected by the predators, while the secondary defenses are used by prey after detection from the predator and thus used to increase the chance of survival from predator's attack (Robinson 1969; Edmunds 1974). Once picked up, preys use different strategies to protect themselves from getting hunted. The secondary defenses may be of various types like stings, horns, hard shell, physical or chemical deterrence, etc. which protect prey from predators in a different way.

## Types of Secondary Defenses

Different animals possess different types of secondary defenses. Some animals may have only one type of defense, while some may have a combination of it. Intraspecific variation in the level of defense has also been seen. For example, some prey in a population may not have any of the defenses (Brower et al. 1970; Broom et al. 2005), while in the other population, there is the presence of defense up to some extent. At the individual level in prey population with defenses, there is considerable variation in the level of defense and also in the precise types of the toxins (Bowers 1992; Holloway et al. 1991; Broom et al. 2005). Different animals use different strategies as secondary defenses against predators. The following are some of the different types of secondary defense mechanisms deployed by prey against predators, once singled out by them.

### Withdraw to Retreat

Many animals prepare a shelter place like crevices and burrows and live within it. They are called anachoretetes. This place is helpful during the

situation of attack from a predator. During the attack, the animals retreat to these hiding places. Some of the retreats are constructed by animals themselves but sometimes natural retreats like hollow tree, vegetation, etc. can be used by animals.

For carrying out important activities like foraging, the animals have to come out from seclusion. Sometimes they come partially out of their retreat, as in case of *Sabella*, or even many times, emergence will be complete. But in both the cases, their activity is limited nearby to their hiding place (Barnard 2004). One example is of hermit crabs (*Pagurus bernhardus*) in which the crabs select the shells very carefully. Generally, two larger crabs initiate the fight to gain access of the shell of smaller crabs (Briffa and Elwood 2001). During the cheliped display, the relative size of crabs is assessed (Neil 1985). It has been shown the contest for shells is started when a crab found its own shell as well as the opponent shell (Dowds and Elwood 1983). During the contest, the attacker raps up the shell by running its walking leg and cheliped over it while the defender withdraws himself within the shell (Briffa and Elwood 2001). Therefore, the assessment and proper selection of retreat site is important as it affects survival rate of prey from attacker.

### Flying Behavior

In animals like an impala (*Aepyceros melampus*), wildebeest (*Connochaetes* sp.), etc., flight behavior is one of the common defense mechanism after getting detected by prey. Between herbivores and carnivores, speed and agility seem to be most obvious and coevolved adaptation.

Fast and sustained speed comes with a cost and various sacrifices like body mass. The flight behavior can be enhanced in two ways.

### Protean Behavior

In this type of flying behavior, the animals run in an uncertain and unpredictable way. For example, the rabbits and gazelles run in zigzag manner. The unpredictable and random changes in direction of running confuse the predator and make it difficult for the predator to keep track of the prey.

### Flash Behavior

In this type of flight behavior, the prey runs for a short distance and suddenly stops and freezes. Immobile animals discourage certain animals, and they don't tend to attack them, and also sudden activity and then complete freezing of prey animals confuse predators (Barnard 2004). The flash behavior is accompanied by bright markings or conspicuous coloration in some organism. For example, the scales of fish produce flash when they turn. Exhibiting conspicuous colors and noise during fleeing is postulated to hinder the location of prey (Loeffler-Henry et al. 2018).

### Diversions

Sometimes, prey has features which divert the attention of their predators from them or their young ones or their vital organs like heads or wings. Autotomy is also one of the ways by which prey divert the attention of the predating animal. Autotomy is the process in which the organism sheds one of its organs voluntarily. The most common example for autotomy is a common lizard. When attacked, they shed their tail which can show movement for around 30 min for which they use anaerobic metabolism (Sanggaard et al. 2012; Dial and Fitzpatrick 1983). As in the case of sustained high speed, the autotomy also has some cost. The organs shedded by the organism may play a vital role as in the case of some lizard species. In the lizard, the tail acts as a fat storing organ and thus is important for them. So, the lizard visits back to place where it shedded the tail and eat its own autotomized tail (Clark Jr 1971; Sanggaard et al. 2012).

Many organisms, to save themselves from predation, have developed eye-like spots (Stevens 2005; Smith 2014; Osterloff 2018), for example, peacock pansy butterflies (*Junonia almana*) which have eyespots on their wings (Fig. 1). It diverts the attention of predators. For the evolution of eyespots, two hypotheses are given, which are as follows (Stevens 2005): **(i) Intimidation hypothesis**, the butterflies intimidate predator by their own enemy which gives them time to flee away. **(ii) Deflection hypothesis**, according to this hypothesis, eyespots are evolved to divert the attack of predators to non-vital organs.

Similar to eyespots, some butterflies have evolved false head. It is hypothesized that the evolution of the false head is an anti-predation adaptation in butterflies as it serves the function of diverting the attention of predators (Robbins 1981; López-Palafox and Cordero 2017). But the role of the false head as anti-predation adaptation is still doubtful as some recent work shows that butterflies are still predated by their natural enemies, mantis (López-Palafox and Cordero 2017).

Many ground-nesting birds perform feigning behavior like broken wing display to distract the predators away from their nest or chicks. The broken wing display is predominantly found in shorebirds like sandpipers. The birds showing broken wing display runs with half-spread wings and drags fanned tail on the ground (Gómez-Serrano and Valenciana-VAERSA 2018). The broken wing display is sometimes combined with other behaviors like injury calls, false feeding, or incubation like displays (Gochfeld 1984; Gómez-Serrano and Valenciana-VAERSA 2018). The intensity of display generally increases from the time of egg-laying to egg-hatching date (Byrkjedal 1989). So, these behaviors and displays of birds increase the breeding success and thus increase the chances of hatching of eggs (Gómez-Serrano and López-López 2016).

Another antipredator strategy used by animals is death feigning or thanatosis. When the predator come very close to the prey or when both come in physical contact to each other, the prey freezes and enters the immobile state and plays dead. Thanatosis reaction was measured using the tonic immobility (Toledo et al. 2010; Humphreys and Ruxton 2018). The tonic immobility state can last from a few seconds to hours and even after the predator threat has been removed. In thanatosis, the animal attains dead-like posture as in the case of the hognose snake (*Heterodon platirhinos*) or *Virginia opossum* (*Didelphis virginiana*), and this posture diverts or may inhibit the attack from the predator (Toledo et al. 2010).

### Deimatic Displays

Deimatic displays serve as surprise element for the potent predators and is used to scare or startle the predators. Generally, the element of

**Secondary Defenses,****Fig. 1** Eyespots on wings of *Junonia almana* (a, b, c)

surprise is some visual component which is hidden (Holmes et al. 2018) and is revealed only when the prey is approached by the predator. For example, when leaf mantis is touched or approached by any predator, it attains the defensive deimatic posture exposing its eye spots, bright colors, and rasping sound (Umbers et al. 2015). Sometimes prey mimics other organisms to produce startle response in their predators (Barnard 2004; Umbers et al. 2015). For example, elephant hawk-moth caterpillar (*Deilephila elpenor*) mimics the head of young pit viper.

**Aposematism**

Many times, the prey possesses both the effective defense mechanism (like sting, toxin, horn, or tough shells) and a warning display depicting

that mechanism (Speed et al. 2006; Wang et al. 2018). Such types of preys are referred to as aposematic prey. Warning displays are used by prey to display the presence of toxins or some other defense weapons with them and thus their unpalatability and unprofitability to the predators. Many aposematic preys prefer olfactory aposematism as warning display where they use noxious odors (Eisner and Grant 1981; Gohli and Högstädt 2009). These odors act both as a warning signal and noxious defense.

Some organisms like poison frog, wood tiger moths, and plain tiger butterflies (Fig. 2) use the bright color display as a warning signal for their toxicity and thus unpalatability (Rojas et al. 2015). Productions of secondary defenses are costly, and thus “cheaters” are found among the aposematic population. Some mutants of a

**Secondary Defenses, Fig. 2** Aposematism in *Danaus chrysippus*. These butterflies contain toxic in them and thus are unpalatable. They display their toxicity by bright coloration

**Secondary Defenses, Fig. 3** Stotting in Thomson's gazelle (*Eudorcas thomsonii*)

population without any defense mimic those organisms of the same population which have an effective defense mechanism for protection from the predator. Such mimicry is called auto-mimicry (Speed et al. 2006; Rojas et al. 2015). In certain cases, the organism mimics another organism which already has some defense mechanism. Such type of mimicry is called Batesian mimicry (Barnard 2004).

Some other strategies used by animals for their defense against predator animals are “mobbing” and displaying “alarm signals.” Mobbing is a cooperative behavior in which individuals of a group attack or harass a predator altogether. It can simply be defined as assemblage or formation around potential predator. This kind of behavior is usually seen for protection of offspring. Alarm signals refer to strategies used for alerting the members of same species, which may be exploited by others in certain cases. Alarm signals can be visual, chemical, auditory, tactile and even electrical channels. Stotting is one type of alarm display used generally by ungulates like gazelles, deer, etc. This is a display in which animals under attack or when is alarmed by the presence of the predator start to jump with stiff leg where all feet leave the ground simultaneously (Fig. 3). Stotting is also used by animals to draw the attention of predators away from their fawn and to attract them toward themselves or used by fawn to alert its mother when it is disturbed while hiding.

## Conclusion

There is always arms race between predator and prey. To sustain in nature, predators need to hunt on prey, while for sustaining, the prey needs strategies to protect themselves from predators. So, both are always coevolving and under pressure of arms race. Prey has evolved adaptation and different types of secondary defenses to protect them from predation when the first line of defense fails. They have evolved aposematism to warn the predators for the presence of toxins; some insects like *Pachyrhynchus* weevils have evolved hard shells to protect themselves from getting hunted.

## Secondary Sex Characteristics

Lisa M. Paciulli and Carmen M. Cromer  
North Carolina State University, Raleigh,  
NC, USA

## Definition and Introduction

Secondary sex characteristics (SSC) in animals are traits that develop after sexual maturity. Unlike

primary sex characteristics such as sexual structures or organs that are directly related to sexual reproduction, secondary sex characteristics seem to be indirectly related and likely increase mating opportunities. Increased mating opportunities often result from individuals being chosen because they appear more attractive to the opposite sex, have better courtship behaviors, and/or are able to out-compete competitors.

## Sexual Dimorphism

Many SSC are also sexually dimorphic. Sexually dimorphic traits are those that differ between the sexes. Secondary sex characteristics and sexually dimorphic traits are highly variable in animals and encompass differences in size, coloration, mass, and behavior.

Sexually dimorphic characteristics that pertain to the body are categorized as sexual size dimorphism. Frequently, one sex is larger than the other (body mass dimorphism). This type of dimorphism can be seen in many taxa. Females are larger 86% of the time when body mass dimorphism is present, which is known as reverse size dimorphism (RSD) (Fairbairn 2013). Throughout most of the animal kingdom – including insects, amphibians, reptiles, and fishes – the females are larger (Fairbairn 2013).

Reverse size dimorphism is less common in mammals and birds, but exceptions exist. Examples of avian and mammalian RSD can be seen in spotted hyenas (*Crocuta crocuta*), baleen whales (Mysticeti), and birds of prey (Falconiformes). Alternately, males are larger 14% of the time. An extreme example is the cichlid fish (*Lamprologus callipterus*). In this species, males are almost three times longer than females.

According to Rensch's rule, male-biased size dimorphism increases with the size of a species, and female-biased size dimorphism (i.e., reverse size dimorphism) decreases. Although this rule does not apply to many lineages, it is present in even-toed ungulates, pinnipeds (seals), and primates. To illustrate, small primates such as tarsiers and galagos exhibit less size dimorphism than monkeys and apes.

SSC may also be expressed as skeletal sexual dimorphisms, such as the elongated tusks seen in male narwhals (*Monodon monoceros*) and Asian elephants (*Elephas maximus*). A subtler example of skeletal dimorphism occurs in the gorilla, skull that facilitate temporal (near the temples) and nuchal muscular (back of the neck) development.

## Biological Ornamentation and Color

One obvious way that secondary sex characteristics vary is via ornamentation and color. Species in which males and females differ by color are said to exhibit sexual dichromatism. Most male birds (Aves) are more ornamented and colorful than females. For example, male red junglefowl (*Gallus gallus*) have long and arching feathers in their tails that appear black but have shiny blue, green, and purple colors compared to the lackluster females.

Many male mammals are also more ornamented and colorful than females. Male bearded pigs (*Sus barbatus*) and Nubian ibex (*Capra nubiana*) have more distinctive beards than females. Male elephant seals (*Mirounga spp.*) and proboscis monkeys (*Nasalis spp.*) have enlarged noses, while male baboons (*Papio hamadryas*, *Papio papio*) and geladas (*Theropithecus gelada*) have thick manes that females do not possess.

Some SSC appear to be influenced by different selection pressures (factors that drive evolution) on the different sexes, and as a result, often vary within a single species. Male eclectus parrots (*Eclectus roratus*) are green, which helps them blend-in with foliage, and appear less detectable to predators when they forage alone for up to 11 months, while females defend nest hollows (Heinsohn 2008). The males' green plumage is shiny and has ultraviolet (UV) pigmentation, which is less visible to predators, but obvious to other parrots. Female eclectus parrots are brightly colored too, but instead of being green, they are red-and-blue. This coloring can be seen by parrots from a distance, letting others know that a nest hole is occupied (Heinsohn 2008).

Colorful females seem to be a pattern in some bird species. Nonmigratory female birds are more

likely to engage in conflicts over territories and resources, and face more intrasexual competition. As a result, they tend to be as colorful as males of the same species. The color serves as a signal to other females that the territory can be defended (Simpson et al. 2015). In contrast, migratory female birds face less intrasexual competition over territory and resources and tend to be less colorful than males. This is likely because they no longer experience selective pressure to signal their status (Simpson et al. 2015).

## Female Choice

In general, females choose to spend time and/or mate with more ornamental and brightly colored males, which is called female choice. Female common roaches (*Rutilus rutilus*) choose the males with the most elaborate breeding tubercles (Kortet et al. 2004). Also, female stalk-eyed flies (*Diasemopsis meigenii*) are more likely to consort with males that have enlarged accessory glands and preferentially mate with males that have exaggerated eye-spans (Chapman et al. 2017). Female wolf spiders (Lycosidae) choose males with ornamental tufts, which are used in leg-waving displays during courtship (Hebets and Uetz 2000).

Among fish, female yellowhammer (*Emberiza citronella*) spend more time in front of, and perch more, beside the most colorful males (Sundberg 1995). Female guppies (*Poecilia reticulata*) have demonstrated choice for males with complex color components and patterns including iridescent blues, violets, greens, and silver; orange, red, and yellow spots; and black and brown spots, bars, and fuzzy markings (Brooks and Endler 2001).

Female pied flycatchers (*Ficedula hypoleuca*) mate preferentially with more brightly coloured males, while female birds of paradise (Paradisaeidae) choose males with elongated and elaborate feathers that extend from the beak, wings, tail, or head. Blandly-colored female quetzal birds (Trogonidae) mate with males that are the most iridescent green and that grow the longest colorful train of tail feathers during the mating season.

Upon closer inspection, even bird species that humans perceive as mostly monochromatic (one main color) may have color differences that appeal to the opposite sex. European starling (*Sturnus vulgaris*) males have feathers with UV colors that humans cannot see. Female birds in these species can see the UV colors, and select males that have the brightest ones (Bennett et al. 1997).

Although most male lions (*Panthera leo*) live in the sweltering heat of Sub-Saharan Africa, they have thick manes akin to humans wearing winter scarves. One reason may be that females mate with the darkest and most decadently maned males (West and Packer 2002).

Female selection of secondary sex characteristics in males is also common in primates. For instance, during the breeding season, male squirrel monkeys (*Saimiri*) use water and fat to increase their body mass approximately 25%. Females choose the largest male squirrel monkeys. In addition, adult male mandrills (*Mandrillus sphinx*) exhibit more colorful red, white, and blue faces and ano-genital regions than females. Likewise, mature male drills (*Mandrillus leucophaeus*) have a pink lower lip, red and lilac genitals, and blue, purple, and lilac bottoms. In both species, the males with the brightest colors have the highest rank in the dominance hierarchy, and the females choose them over subordinate males. However, because dominant males usually can control whether or not lower-ranked males have access to females, it is difficult to tell whether females are actively choosing dominant males or mating with them because they are the only males with whom they are “allowed” to mate. This situation is clear in orangutans (*Pongo*) where females have been observed actively guiding the penises of males that have well-developed face flanges (cheek pads) into their vaginas, and rejecting matings with subadult males and males with undeveloped flanges.

Moreover, females choose males with exaggerated traits that do not exist in nature. For instance, female vinegar flies (*Drosophila serrata*) show preferences for male cuticular hydrocarbons (specialized exoskeletons) and combinations of

traits that do not occur in natural males (Van Homrigh et al. 2007). Also, female long-tailed widowbirds (*Euplectes progne*) choose males with tails that have been artificially lengthened by researchers (Andersson 1982).

Behavior can also be considered a secondary sex characteristic. Female field crickets (Gryllinae) select males that call for longer periods (Hedrick 1986), while túngara frogs (*Engystomops pustulosus*) prefer males with elaborate “chucks” in their mating calls (Ron 2008). Also, male warblers with larger song repertoires mate earlier than those with smaller repertoires (Catchpole 1980).

## Males Can Be Choosy Too

Reproduction, gestation, lactation, and other offspring care are so energetically expensive for females that females should only invest in growing elaborate secondary sex characteristics when they outweigh the energy it costs to produce those traits. Males may select females with these enhanced traits. For example, in some fly species (Empididae), the females’ dark wings, inflatable abdominals sacs, and feather-like scaly legs may make them more attractive to males. Males choose one of the swarming females to be the recipient of his nutritious silk-wrapped prey item “nuptial gift.”

Female slender-necked shorebirds (*Phalaropus spp.*) are larger and more brightly colored than males. After males choose a female with which to mate, they then incubate the clutch of eggs and care for the hatchlings. Male Gulf pipefish (*Syngnathus scovelli*) invest in offspring care as well, which is a hot commodity. Correspondingly, female pipefish have brighter abdomens than males. Males choose to mate with, and provide offspring care to, the females with the most and/or largest silvery blue iridescent abdomen bands.

## Bright Male Hypothesis

It is overwhelmingly clear that females, and in some cases males, select the most exaggerated

ornaments and colors, but why? The “Bright Male” hypothesis proposes that ornaments and bright colors advertise a healthy condition free of disease and parasites (Hamilton and Zuk 1982). The idea is that if an individual was sickly, it would have to expend energy healing rather than growing extra-large and/or colorful traits. Healthy individuals would then pass on the beneficial and desirable traits to their progeny.

Most female animals should be picky and select males with advantageous traits so their offspring inherit them. Because reproduction and offspring care are so draining for females, it is even more important that they choose to reproduce with males that possess characteristics indicative of the highest genetic fitness. When individuals choose to mate with those that possess the traits they most desire, it is called sexual selection. Sexual selection was first proposed by Charles Darwin (1871) to explain the exaggerated and colorful characteristics of male peacocks (*Pavo cristatus*). Darwin (1871) discussed how a combination of female mate choice (females choosing to mate with the most colorful males) and intrasexual competition between males for mating opportunities with females were likely responsible for the peacock’s ornaments and colors.

Sometimes it is difficult to tell if sexual selection is at work or some other mechanism. For example, during peak fertility, female brown capuchins (*Sapajus apella*) only solicit matings with the dominant male. If the dominant male is replaced by another male, the females will no longer mate with him, even though the previous dominant male still possesses the same genes, but a different rank. This makes it likely that females are not selecting the dominant male for his genetic fitness, but rather for his ability to protect the offspring he likely fathered.

Male northern cardinals (*Cardinalis cardinalis*) are a vibrant crimson red, while the females are a duller red-olive. Female cardinals practice assortative mating, which means that they mate with individuals that resemble themselves. Females with red bills choose to mate with males that have the reddest bills (Jawor et al. 2003). These males also have better body conditions than males

with lighter red bills. House finches (*Haemorrhous mexicanus*) have orange-reddish coloring in their crowns and plumage related to carotenoid pigments in high quality foods like seeds. Female house finches choose to mate with brighter males, and these males appear to be better food providers for the females and hatchlings (Hill 1990).

For months every spring, male sage grouse (*Centrocercus minimus*, *C. urophasianus*) perform an elaborate courtship ritual on leks (groups of males competing to mate) for several hours. They expand white air sacks on their chests, make soft drumming noises, extend their tail feathers, and strut around in front of drabber-colored females. The females tend to choose males that strut more and vocalize in a specific manner, and these males end-up having the greatest reproductive success that season (Gibson and Bradbury 1985).

A demonstrative example of biological ornamentation serving a primarily decorative function instead of a utilitarian one is the previously mentioned Indian peafowl's (*P. cristatus*) grand plumage. Male peacocks have bright plumage and long tail feathers decorated with eye-spots. Female peahens are duller in color and choose to mate with the peacocks that have the largest eye-spots. Eye-spots serve as signals of the owner's health and vitality because peacocks with larger eye-spots have progeny that weigh more and live longer than the offspring of peacocks with smaller eye-spots (Petrie 1994).

Along with intersexual (between the sexes) selection for attractive traits, body size and armaments used as weapons may result from intrasexual (within a sex) selection to win battles for access to females. For example, male hissing cockroaches (*Gromphadorhinini*) have pronounced horns (chitinous protrusions) on top of the pronotum (plate-like thoracic structure) that are used during fights. Also, the largest male teiid lizards (Teiidae) win more fights, mate with more females, and produce more offspring than smaller males (Anderson and Vitt 1990). The antlers of deer bucks, many antelopes and goats (Bovidae), as well as the horns of male dung beetles (Scarabidae) and Hercules beetles

(*Dynastes hercules*) are used in male-to-male competition for females. Female deer select males with larger antlers, and the larger the antler, the more likely a male is to fight off other males and control a harem (group) of females.

## Immunocompetence Handicap Hypothesis

The Bright Male hypothesis makes sense, except when one considers that many of the traits that are being selected for could increase the likelihood that the owner dies and/or gets sick. For example, shiny colors could make an individual stand-out to predators, while heavy appendages could slow down an individual trying to escape danger. This means that the individual's genes could be removed from the gene pool quicker than those that do not possess the "sexy" traits. Thus, secondary sex characteristics can be energetically costly and leave organisms vulnerable to predation, illness, and parasitism.

Although male peacocks with larger eye-spots and longer/heavier trains enjoy higher reproductive success, they also expend more energy growing those feathers and have weaker immune systems. Likewise, although female great tits (*Parus major*) choose males with larger breast-stripes because they are more dominant and potentially show greater parental investment, those males have worse body conditions and suffer greater mortality during periods of cold weather (Moore et al. 2015). How then do secondary sex characteristics that increase mortality persist in a population?

There seems to be a trade-off between sexual ornamentation, bright coloration, and the negative consequences resulting from them. The "Handicap Principle" (Zahavi 1975) offers an alternate explanation as to how seemingly disadvantageous traits and behaviors can be maintained – and selected for – within a population. Crucial to this hypothesis is the idea that the handicaps are signals of health, as only the fittest individuals could afford to squander resources to grow and maintain the traits (Roberts et al. 2004). For instance, the antlers of male deer (Cervidae)

grow fast and are energetically and nutritionally demanding because deer regrow antlers every year. This means that antlers can be considered an “honest signal” of food-gathering ability and health, conveying information that would increase a female and her offspring’s fitness, should she choose to mate with a male with a strong signal.

In males, androgens stimulate the development of SSC, but also impair the immune system. Under the “Immunocompetence Handicap” hypothesis (Folstad and Karter 1992), the immunosuppressive effects of testosterone indirectly signal an animal’s capacity to withstand sickness, as only the healthiest individuals maintain the high levels of androgens required for sexual signalling. Accordingly, in reptiles and birds, there is a negative correlation between testosterone and immunity. For example, male European starlings (*S. vulgaris*) implanted with testosterone showed lowered immune responses (Duffy et al. 2000). However, this hypothesis does not seem to hold for all taxa. For example, there is not a strong correlation between testosterone and lowered immunity in mammals (Roberts et al. 2004).

### Fisher’s Runaway Hypothesis

Furthermore, according to Fisher’s Runaway Hypothesis or Runaway Selection (Fisher 1915), extreme secondary sex characteristics/sexual dimorphism can occur because: (1) females preferentially mate with males that have certain characteristics, and (2) offspring inherit their father’s characteristics, as well as their mother’s preferences for them. Together, this leads to a “runaway” effect through which increasingly exaggerated traits evolve in one direction (directional selection). An example is Wilson’s bird-of-paradise (*Diphyllodes respublica*). Males of this species have evolved extreme ornamentation and coloration that includes bare blue headskin, a velvet green breast, a scarlet back, and two curved violet tail feathers. Male Wilson’s birds of paradise clear an area and perform a complex dance ritual that females use to determine with whom to mate.

### Primary Hormonal Controls

In most vertebrates, secondary sexual characteristics (SSC) are mediated by the hypothalamic–pituitary–gonadal (HPG) axis. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates gonadotropic cells within the anterior pituitary to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In response, LH and FSH act on the gonads (ovaries or testicles) to produce sex hormones (estrogen, testosterone, progesterone, etc.) that trigger either follicle growth or spermatogenesis. In females, LH causes the ovaries to secrete estradiol and progesterone, while in males, LH causes the testicles to secrete testosterone. It is through this hormonal cascade that sexual maturity occurs and SSC develop.

### Secondary Hormonal Controls

Some hormones peripheral to the HPG axis also influence SSC. For instance, in mice, GnRH-1 (the mammalian variant of human GnRH) is upregulated by the neuropeptide kisspeptin. The hormone leptin, produced by adipose (fat) cells, also appears to upregulate GnRH. For this reason, increased body fat can indirectly modulate SSC through the actions of leptin. GnRH can also be downregulated by the hormone inhibin. Upregulation refers to an increase in receptors for a particular type of hormone, while downregulation refers to a decrease.

### Species-Specific Hormonal Controls

To reach sexual maturity, most insects, unlike vertebrates, undergo metamorphosis. The process of metamorphosis is under endocrine control. In the brain, prothoracicotropic hormone (PTTH) is released, stimulating the prothoracic glands to secrete ecdysone, a hormone that induces molting. In females, juvenile hormone (JH) stimulates egg production. Relatively little is known about what hormonal factors control SSC in imagoes (adult insects). Nevertheless,

insects exhibit some of the most vivid SSC that are sexually dimorphic in the animal kingdom. Notably, male honeybees (*Apis*) lack stingers and do not partake in resource collection, while male fruit flies (*Drosophila*) have evolved sex combs (chitinous bristles on the forelimbs) that facilitate successful courtship.

In fish, SSC are mediated by the HPG axis. In addition, many species of fish are capable of sequential hermaphroditism (switching sex). This process has been linked to the enzyme aromatase, which catalyzes estrogen from androgens.

A distinguishing feature of nonmammalian sexual behavior is the nonapeptide arginine vasotocin (Maney 2010). In male túngara frogs (*Engystomops pustulosus*), vasotocin injection leads to increased calling behavior and sexual advertisement (Kime et al. 2007), suggesting that vasotocin is an important modulator of SSC in amphibians. Generally, in reptiles, SSC are either reduced or limited to differences in size. One prominent exception is male Carolina anoles (*Anolis carolinensis*) that have bright red dewlaps that females lack.

Like mammals, birds achieve sexual maturity and develop SSC through the HPG axis. However, birds rely heavily on visual cues to signal fitness. As a result, raised testosterone levels in males correlate positively with raised levels of carotenoids, which includes most of the pigments involved in feather and beak coloration (Blas et al. 2006). Also, the peptide hormone prolactin (PRL) directs parental care in many passerines.

### Chemical Controls and Endocrine Disruption

The endocrine system is vulnerable to a class of exogenous compounds (produced outside cells, tissues, organisms) known broadly as endocrine disruptors. These compounds can be natural or synthetic and include phthalates, oxybenzone, tributyltin (TBT), dichlorodiphenyltrichloroethane (DDT), and xenoestrogens such as polychlorinated biphenyl (PCB) and bisphenol A (BPA), among others. These compounds affect the endocrine system by either mimicking natural

hormones and/or binding to receptors and blocking the actions of natural hormones.

Industrial advances in production and use of plastic has led to increased accumulation of endocrine disruptors in the environment. As a result, adverse effects have been observed in insects, fish, reptiles, birds, and mammals, including humans. The extent to which endocrine disruptors affect wildlife remains unclear, but there is an increasingly large body of evidence demonstrating that endocrine disruptors cause deformities, alter neurological function, shorten pubescent timelines (in humans), change sexual behavior, reduce fertility, and lead to masculinization and/or feminization. Inducing masculinization or feminization affects the expression of SSC.

For example, fathead minnows (*Pimephales promelas*) exposed to bleached sulfite mill (BSM) experience profound changes in sexual development, including increased size and masculinization (Parrott et al. 2004). Likewise, the use of TBT on boats causes female common periwinkle sea snails (*Littorina littorea*) and related taxa to develop male sex organs, a condition known as imposex. TBT has also been shown to cause estrogenic activity in mice (Penza et al. 2011). Further regulation is necessary, as endocrine disruptors not only affect SSC but pose health risks to both wildlife and humans.

### Environmental Controls

Maintenance of SSC is sensitive to environmental cues. Because the hypothalamic–pituitary–adrenal (HPA) axis works in tandem with the HPG axis, factors that influence the stress response can in turn affect sexual function. For instance, chronic stress may lead to cessation of the menstrual cycle in human females. Other important cues are seasons, light, and food availability, which regulate HPG activity in many species of vertebrates. Food availability also regulates the SSC of invertebrates. This has been demonstrated in male wolf spiders (*Schizocosa ocreata*). When given access to more food, they develop larger forelimb tufts, a trait selected for by females (Hebets and Uetz 2000).

Similarly, intersexual and intrasexual interactions can cause hormonal fluctuations, leading to changes in SSC. When male song sparrows (*Melospiza melodia*) are exposed to other males, their testosterone levels increase (Moser-Purdy et al. 2017). Similar occurrences have been observed in mammals. Subordinate female marmoset monkeys (Callitrichidae) have low levels of GnRH and do not ovulate. Thus, gene-environment interactions underlie the development and maintenance of SSC.

## Sex Differentiation and the Environment

Chromosomal sex is determined at conception. The XY sex-determination system is found in most mammals, while the ZW sex-determination system works in birds, as well as some insects, reptiles, and fish. Conversely, sex differentiation is under hormonal control and can be modulated by environmental factors. Thus, different developmental environments can lead to functionally significant differences in the size and shape of male sexual traits, such as cryptorchidism (failure of the testes to descend). Developmental responses to different ecological conditions produce trait variation and can lead to selection and subsequent genetic accommodation of the plastic phenotypes (an individual's physical traits). For example, male and female water fleas (*Daphnia magna*) reared in the presence of diethylstilbestrol and methoprene show rapid sexual development (Olmstead and LeBlanc 2000).

## Conclusion

In humans, secondary sex characteristics develop at the onset of puberty (the stage at which a person becomes capable of sexually reproducing). Classic examples of human SSC are differences in fat distribution and voice pitch. In nonhuman animals, secondary sex characteristics (SSC) develop after individuals reach sexual maturity and can take many forms. SSC may manifest as differences in body sizes/masses, shapes, ornamentations, colors, and

behaviors, and most seem to be subjected to sexual selection by females on male traits. SSC are also mediated by various hormones and can be affected by environmental factors. Of particular concern are xenoestrogens, which cause endocrine disruption in a variety of taxa. Endocrine disruption can lead to feminization/masculinization, changes in sexual behavior, reduced fertility, etc., which can affect the expression of secondary sex characteristics, as well as the health of the individual.

## Definition

The selection study is the study of the basic mechanism by which nature ensures better adaptation, survival, and selective reproduction of some animals as compared to other animals. Natural selection plays an important role in the development, maintenance, inheritance, and variability of simplified algorithms for decision-making in animals, that are otherwise capable of only limited computational power and memory (Bach and Dayan 2017). It is frequently observed that selectively bred domesticated animals behave very differently from their wild counterparts. It implies that behavioral changes in animals are occurring in response to their surrounding environment. The cognitive system helps animals to adapt and alter their behavior according to the demands of the environment. They can also be at certain times under positive

or negative selection depending on the extent of variability in the environment.

To understand the extreme variability of behaviors within and among species, selection has been studied with the help of two different yet complementary perspectives: ultimate and proximate studies (Bateson and Laland 2013). Ultimate studies examine ecological or social determinants of natural selection that lead to the evolution of a specific behavior without considering the cognitive mechanisms underlying these behaviors. Darwin in his famous book “Origin of Species” proposed the famous theory “Survival of the fittest,” which emphasized the role of behavior adaptation to complex social and ecological situations for better survival.

On the other hand, proximate studies establish the correlation between behaviors that have been favored by natural selection and mechanisms underlying the evolution of key biological structures including neural and developmental aspects. In a way, proximate studies report that the cognitive functions or neural structures evolve along with the evolution of species; collectively known as phylogenetic studies. Phylogenetic studies can reveal constraining factors that limit the evolution of a more complex form of cognition. Evolutionary psychologists believe that like any other biological trait, animal behavior too undergoes the process of natural selection and this evolutionary approach should be used to understand the evolution of animal mind. Furthermore, studying the role of natural selection on cognition and neural structures can help shed light on why specific abilities or mechanisms arose in some species but not others.

Alfred Lotka (1926) believed that there were mechanisms within a body that enable the organism to make evolutionarily good decisions: He pointed at an evolved neurological basis and an ability to predict that controls decisions. However, behavioral ecologists argue that the animals use emotional motivation, and learning to process and implement in the decision-making process (Frankenhuis et al. 2018; Higginson et al. 2018).

## Conclusion

Thus, it can be inferred that natural changes in the environment as well as evolutionary changes within the organism itself determine animal decision-making ability, which plays a major role in the natural selection of animals (Mobbs et al. 2018).

## Definition

Self-administration is a technique used in animal behavior, which relies on operant conditioning processes. Self-administration involves a process whereby an animal performs a particular behavior to receive a rewarding stimulus of some kind – generally a drug, food, or liquid such as water or alcohol but can also include stimulation of brain reward areas. The learning of this behavior is termed instrumental learning and is an operant conditioning process whereby an action becomes associated with an outcome (delivery of rewarding stimulus). Self-administration has many applications and is considered the gold standard test for assessing the potential abuse liability of new pharmaceutical compounds in a preclinical setting. The substance is considered to be of high abuse potential if the animal will self-administer it readily. Self-administration in a laboratory setting is typically performed by rats but can also be performed by any species capable of operant learning, e.g., humans, nonhuman primates, pigeons, mice, and even honey-bees.

## History and Apparatus

Self-administration originated in the laboratory of eminent psychologist B. F. Skinner and is

inextricably linked to his theory of learning called operant conditioning, a theory which focuses on the linking of behavior with rewards/consequences (Skinner 1938). B. F. Skinner created the first self-administration chamber (colloquially referred to as a “Skinner Box”). The apparatus typically consists of an enclosed chamber, which contains, at its simplest, a lever or nose-poking device and a receptacle where liquid or pellet rewards can be delivered. Performance of the reward-paired operant response results in reward delivery. Many permutations and applications of this paradigm now exist and the self-administration apparatus is tailored to each application, route of administration, and species.

### **Motivation and Reinforcement: Central Tenants of Self-Administration**

According to operant conditioning theory, reinforcement occurs when after a particular operant response the outcome results in an increase in the probability of another response being performed. Reinforcement can be positive, i.e., involve the consumption of a rewarding stimulus, or negative, i.e., involve the removal of an aversive stimulus. Both types of reinforcement increase the probability of another response being performed. In this context, a rewarding stimulus is termed a positive reinforcer and an aversive stimulus is termed a negative reinforcer. When an aversive stimulus or removal of a rewarding stimulus is paired with the behavioral response, the process is termed punishment, as the behavioral response is less likely to occur as a result of the stimulus.

Though the work of Skinner does not focus on the internal states and drives that result in an operant response, it should be acknowledged that the concept of appetitive motivation is a fundamental aspect of positive reinforcement and therefore self-administration. The stimulus is considered to have primary (or unconditioned) reinforcing properties, which elicit approach behavior towards the reward-paired operandum (e.g., lever). Reinforcers are also referred to as goals, incentives, or rewards and these terms embody this concept of appetitive motivation.

It is useful to distinguish between the appetitive and consummatory aspects of the behavior involved in self-administration. An animal self-administers because they have a drive to obtain the reward (e.g., a sugar pellet). Appetitive behavior is that which increases the likelihood of obtaining this reward, e.g., increased approach behavior towards the reward-paired operandum, increased performance of the operant response. By contrast, consummatory behavior is that which is involved in the consumption of the reward (i.e., satisfaction of the need), for example, licking, chewing and swallowing are considered consummatory behaviors.

Operant learning in the initial stages of self-administration is driven by action-outcome contingencies, where an animal learns to perform a particular behavior based on the value of the outcome. For example, if pressing on a lever results in delivery of palatable food, an animal will generally readily learn this response. As a result the operant response to obtain the palatable food is considered goal-directed (the rewarding stimulus is the goal towards which the animal is directing their behavior). However, if the food is devalued, through satiety or conditioned aversion, the animal will reduce or cease responding. It should be noted that extended periods of self-administration can eventually lead to habitual responding that is resistant to devaluation.

### **Free Access**

Though self-administration typically involves engaging in an operant response (e.g., lever press) to obtain a specified amount of a rewarding substance, the simplest form of self-administration involves giving free access to a particular substance and monitoring intake. Obviously the manipulations possible in this sort of experiment are more limited and there is no appetitive component to the self-administration behavior; however, basic consummatory information can be obtained which can be useful when working with lower order species such as invertebrates. Examples include experiments using *drosophila* or ants, which measure the amount of sucrose or ethanol the insects consume. It is also possible to give a choice between two substances, e.g., the

two bottle free choice paradigm in alcohol research will give the subject free access to both ethanol and water in the home cage and the preference of the subject for ethanol as compared to water is measured. It should be noted that these basic consumption experiments, though sometimes referred to as self-administration, are not generally considered “operant self-administration” as there is no distinction between the operant response and the consumption of the reward.

### **Operant Self-Administration (Skinner Box)**

The type of self-administration that everyone is most familiar with is that performed in an operant conditioning “Skinner box” and generally involves pressing a lever, the pecking of a response key, or the breaking of an infrared beam with a nose poke. Though one operandum is sufficient, there is usually the choice of two and one will be paired with reward delivery. Responding on the other will result in no programmed response or the delivery of a control substance (nonrewarding) such as saline or water. The inclusion of a 2nd operandum allows the experimenter to determine that the animal is responding for the reward and not just engaging with the operandum per se.

The operanda used in various self-administration setups are tailored to the abilities of the species in question and the type of experiment being performed. Ideally it is something that the animal will readily engage with when exploring their environment because this is how the first operant response occurs. Operanda are typically levers or nose-poking devices, although modern versions of Skinner boxes can also have touchscreens with digital displays. Skinner boxes for pigeons will have a response key, which detects mechanical pressure and the pigeon learns to peck this key. Nonhuman primates given their high levels of dexterity can learn to press buttons or perform sophisticated tasks to self-administer rewards such as drugs or orange juice. In the runway task, the operant response is actually the movement of the animal (usually a rat) towards the goal box. Once the animal reaches the goal box, it will receive an administration of drug.

The reward can be in the form of a food pellet (delivered by a dispenser) or a small amount of liquid delivered into the receptacle (e.g., liquid sucrose or ethanol) or straight into the mouth. If the reward is a drug, this is usually delivered intravenously through a catheter (often a jugular vein or tail vein catheter). Animals can also learn to perform an operant response to receive intracranial stimulation of reward areas in the brain. This stimulation can be electrical or optical (using light to activate channels that have been inserted into the brain using a viral vector). Cues (e.g., lights or tones) are often paired with reward delivery and these act as a discrete cue which can then be used to precipitate reward-seeking behavior. When discriminative stimuli (denoted S+), otherwise known as occasion setters, are present in the chamber, it is indicating that the operant behavior will be reinforced. Responding usually increases in the presence of these cues.

### **Typical Self-Administration Procedure**

Self-administration typically involves daily sessions for a period of time until the behavior is considered acquired. Once acquired manipulations can be performed, e.g., interventions that are hypothesized to reduce responding for the reward. Sessions can be as short or as long as experimentally required and in some instances the animals are even housed in the self-administration chamber.

### **Schedules of Reinforcement**

Self-administration experiments can adopt different reinforcement schedules to examine different aspects of motivated behavior. A schedule of reinforcement describes the relationship between the response and the reinforcer. Reinforcement schedules can vary both in the number of operant responses required to obtain the reinforcer (ratio) and in how much time must pass before the next reinforcer can be obtained (interval). Stimuli are also often presented to signal reward availability or to coincide with reward delivery. Different schedules of reinforcement produce characteristic rates and temporal patterns of responding that are reasonably consistent across species.

### Fixed Ratio

For fixed ratio (FR) schedules, a fixed number of operant responses are required to obtain a reward. For example, on a fixed ratio of 3 (FR3), every 3rd response would result in reinforcer delivery. The most simple schedule of reinforcement is FR1, whereby every operant response is reinforced (this is also referred to as continuous reinforcement). This type of schedule provides the most direct relationship between operant responding and reinforcer delivery. Increasing the response requirement (ratio) is useful when examining a substance that does not support a high rate of self-administration, such as a high dose of a drug. This means that the rate of self-administration can be low while still maintaining a high level of responding. In general, animals learn more readily on FR schedules than other schedules, especially FR1. While FR schedules are useful for examining patterns and rates of self-administration, they are limited in some respects. For example, a decrease in the rate of responding for a substance is ambiguous and could be interpreted as either an increase or a decrease in its reinforcing efficacy. For this reason, simple FR schedules are not recommended when attempting to assess changes in the strength of the reinforcer (Arnold and Roberts 1997).

### Variable and Random Ratios

For variable ratio schedules, the number of required operant responses varies around an average. For example, a variable ratio of 3 (VR3) might require 1, then 3, then 2, then 5, then 4 responses – an average response requirement of 3. Random ratios are built on a similar principle, except that rather than varying around an average there is an equal probability of any ratio within a range being selected, resulting in an unpredictable average. Both variable and random ratios generally support a steady rate of responding and are particularly resistant to extinction, a phenomenon known as the “partial reinforcement extinction effect” (Lewis 1960).

### Progressive Ratio

For progressive ratio (PR) schedules, the response requirement to obtain a reinforcer systematically

increases. The ratio increase usually follows each reinforcer delivery, but can also occur at the beginning of each self-administration session (Richardson and Roberts 1996). The purpose of the PR schedule is to increase the response ratio up to a point where the animal no longer responds. The highest ratio that the animal achieves in order to obtain one reinforcer is termed the break point, or breaking point. The break point is typically used as a measure of an animal's motivation to acquire a particular reinforcer.

Many different formulas can be used to determine the pattern of ratio increases in PR schedules. The earliest PR schedule, developed by William Hodos to examine the reinforcing efficacy of sweet milk solutions, followed a simple formula where the ratio increased by 2 following each delivery (e.g., 2, 4, 6, 8, 10, 12...) (Hodos 1961). Other PR schedules double the response requirement each time (e.g., 2, 4, 8, 16...) and others follow an exponential function (e.g., 1, 2, 4, 6, 9, 12...) (Richardson and Roberts 1996). The best choice of schedule depends upon many factors including the species of animal, the type of reinforcer, and the session length.

PR schedules have some advantages over FR schedules, in that interpretation of behavior is generally less ambiguous. For example, a decrease in break point suggests a decrease in the reinforcing efficacy of a substance, whereas a decrease in the rate of responding under an FR schedule could indicate either an increase or decrease in reinforcing efficacy. However, it has also been questioned as to whether PR schedules always provide an effective measure of reinforcing efficacy (Arnold and Roberts 1997). For instance, some self-administered drugs can increase locomotor activity which can facilitate operant responding and increase break point, an effect that is independent of the value of the substance (Cantin et al. 2010).

### Fixed and Variable Interval Schedules

For fixed interval (FI) schedules of reinforcement, the first response following a designated period of time results in reinforcer delivery. For example, an FI20 min schedule would mean that the first response following a 20-min interval would be

reinforced. Responses emitted during the interval are not reinforced. The timing of the interval can either begin from the end of the preceding interval, or from the time of the last reinforcer delivery. The former can result in reinforcers being delivered within a shorter time frame than that specified by the interval. It is common for drug self-administration experiments to incorporate a fixed interval between drug deliveries, known as a time out period, to mitigate the risk of overdose. It is also common for some operant tasks, such as touch screen tasks, to incorporate a time out period after an error is made as a form of punishment. FI schedules can also be useful for minimizing the impact of behavioral effects of a drug on responding (Balster and Schuster 1973). Variable interval (VI) schedules of reinforcement work according to a similar principle to FI schedules except that the duration of each interval varies around an average length of time.

#### Tandem, Multiple, and Mixed Schedules

Ratio and interval schedules can be combined to form *tandem* schedules. For example, the tandem schedule FI 20 FR 10 would result in every 10th response after a 20-min interval being reinforced. Mixed schedules are where two or more different schedules alternate (either successively or randomly), and each schedule is signaled by a distinct stimulus. Mixed schedules are the same as multiple schedules except that the schedule change is not indicated by a stimulus.

#### Second-Order Schedules

Under second-order schedules, reinforcer delivery occurs infrequently, following an extended sequence of responses that are maintained by intermittent conditioned stimulus presentations. Second-order schedules are built from two schedules – one schedule dictates the response requirement for conditioned stimulus presentation (often referred to as the component or unit schedule) and another schedule dictates the conditions for reinforcer delivery. Second-order schedules are generally either composed of two FR schedules or a combination of ratio and interval schedules. For example, FI 20 min (FR 10:S) describes a second-order schedule where every 10th response results

in conditioned stimulus (S) presentation, and reinforcer delivery occurs after the 10th response following the fixed interval of 20 min. FR 100 (FR 10:S) describes a second-order schedule where every 10th response results in S presentation and reinforcer delivery occurs after every 100th response. Whether it is best to adopt an FR/FR or combined FI/FR schedule depends upon the purpose of the experiment. FI/FR schedules tend to promote the development of habitual responding that is less sensitive to changes in reinforcer value, whereas FR/FR schedules exert less temporal control over reinforcer delivery (Everitt and Robbins 2000).

Prior to animals being tested on a second-order schedule, they are first trained on a basic FR schedule where reinforcer delivery is paired with presentation of a stimulus. With repeated reinforcer-stimulus pairings, the stimulus itself becomes a conditioned reinforcer, capable of maintaining operant responding. Once stable responding has been acquired, the frequency of reinforcer delivery is gradually reduced. This is followed by a gradual reduction in stimulus presentation until the desired FR or FI is achieved. Omission of the primary reinforcer, conditioned stimulus, or substitution with an unpaired stimulus results in a gradual reduction in response rate (Schindler et al. 2002).

It has been demonstrated that responding under second-order schedules can be maintained with as little as one reinforcer delivery per session (Goldberg and Tang 1977). For this reason, second-order schedules have a major advantage when used in drug self-administration studies, in that a large amount of behavioral data can be obtained while animals are in a drug-free state. This is in contrast to low FR and PR schedules where almost all responding occurs under the influence of drug. This is an important issue to consider given that many self-administered drugs can have behavioral effects that either increase or decrease rates of operant responding. Examination of responding prior to the first drug delivery under a second-order schedule can therefore provide a more accurate measure of a drug's reinforcing efficacy (Arroyo et al. 1998).

The main disadvantage of the use of second-order schedules is the extended training that is required compared to more simple schedules. This is an issue for intravenous drug self-administration studies that are constrained by the length of time that intravenous catheters maintain their patency. Responding under second-order schedules also tends to exhibit more day to day variability compared to low FR schedules (Schindler et al. 2002).

### Chained Schedules

Chained schedules require the completion of a series of linked component schedules that eventually culminate in reinforcer delivery. It is common for each component schedule to be associated with a unique discriminative stimulus. Theoretically, chained schedules can be comprised of any number of components; however, the more components, the less likely it is that the animal will complete the terminal link to obtain the reinforcer. With homogenous-chained schedules, each component schedule requires a similar topographic response, whereas heterogeneous chains require different topographic responses for each link.

Chained schedules are often used in drug self-administration studies to loosely model the sequences of behavior that precede drug self-administration, such as procuring money, purchasing and preparing the drug. Chained schedules can also be used to separate drug “seeking” from drug “taking” behaviors, which are usually represented by the same response in intravenous drug self-administration experiments (Roberts et al. 2013). This is because self-administration of intravenous drug does not require an additional consummatory response like self-administration of food or alcohol (e.g., chewing, licking, swallowing). This separation of drug “seeking” versus drug “taking” is usually achieved by implementing a chained schedule where responding on a “seeking” operandum eventually provides access to a “taking” operandum which then provides reinforcer delivery.

### Concurrent Schedules

A concurrent schedule is where more than one schedule is available for an animal to choose.

The different schedules usually have different response requirements (e.g., FR1 vs. FR10), but can also be combined with different reinforcers (e.g., different types of food, different drugs, food vs. drug), different reinforcer magnitudes (e.g., high vs. low dose of drug), or different reinforcement probabilities (e.g., 100% vs. 25%). The purpose of concurrent schedules is usually to examine an animal’s preference for a particular schedule, and/or how preference can be affected by variables such as changes in unit price.

### Extinction and Reinstatement

Once operant responding for a reinforcer has been acquired it can be extinguished by removal of the reinforcer. Extinction describes a gradual reduction in responding that results from new learning about the action-outcome relationship (i.e., learning that the operant response no longer produces reinforcement). How quickly responding is extinguished depends upon many factors including the value of the reinforcer, the period of self-administration, the schedule of reinforcement and cognitive factors. Extinguished responding can be reinstated by re-exposure to the reinforcer (known as “priming”) or presentation of stimuli previously associated with reinforcer delivery. Extinction-reinstatement paradigms are commonly used in drug self-administration studies to model relapse to drug seeking.

### Applications

Self-administration can be applied to a multitude of research questions and is easily manipulated to experimental needs. It is an ideal technique to study food and drug reinforcement and is therefore commonly used in preclinical drug discovery research to assess whether or not a drug has abuse potential. If an animal will readily self-administer a drug then, it is generally considered to have abuse potential. Self-administration is also widely used in the addiction neuroscience field as a technique to investigate the neurobiology underlying addictive behavior, as inherent to addiction is the administration of the drug being abused. Self-administration is equally as applicable to studies of cognition given that it is based on operant learning processes. This is particularly the case

for touchscreen chambers where a wide array of cognitive tests can be used to screen potential therapeutic compounds for the treatment of conditions such as dementia.

## Synonyms

Awareness; Consciousness; Introspection

Benjamin M. Basile and Emily Kathryn Brown has contributed equally to this work.

## Introduction

Think of yourself. Now, try to imagine what it would feel like to *not* be self-aware. You probably find it difficult. Arguably, it would not feel like anything. Self-awareness infuses human experience. Because human self-awareness is so conspicuous to us personally, it is natural to wonder if it, or any related cognitive process, occurs in nonhuman animals. At the same time, because self-awareness is so private and personal, the role it plays in behavior is difficult to articulate, much less study scientifically. The difficulty in studying subjective conscious awareness has long troubled psychology and especially comparative psychology. In 1932, Edward Tolman highlighted the problem by saying:

And, if psychology could only be content with the lower animals, and preferably with rats, and not try to mess around with human beings, this whole question of consciousness and ideas might well have been omitted. But human beings insist upon being included in any psychological purview. And they insist that they are conscious and do have ideas – however improbable this latter may often appear. The shameful necessity, therefore, devolves upon us of having to invent some sort of an hypothesis as to these matters. Our attempts, however, will be but mere guesses. (p. 204)

Here, we address the broad concept of self-awareness and how it has been defined. We next address the challenges that scientists have faced in operationalizing that definition in a way that would be testable in nonhuman animals. We then describe three major areas of study that have each been described as informing our knowledge of self-awareness in nonhuman animals: metacognition, theory of mind, and mirror-guided behavior. For each, we attempt to bracket what we do know, and can know about nonhuman self-awareness, by presenting both liberal and skeptical interpretations. We end by returning to Tolman's conclusion, updating it to reflect that, although there will probably never be consensus about the question of nonhuman self-awareness, the efforts to answer it have not been wasted, as they have revealed a wealth of knowledge about more-tractable issues of comparative cognition and behavior.

## Defining Self-Awareness

Self-awareness is both subjectively obvious to us and objectively obscure. Ask your colleagues, and they will all likely tell you that they “have” self-awareness. However, ask them to provide a definition of self-awareness, and most will stumble and hedge. Further, ask them to provide a set of objective behaviors that would unambiguously indicate self-awareness in another human, animal, or machine, and few of them will be able to agree on the criteria.

Self-awareness is one of the oldest subjects of philosophical and psychological study and thus has been assigned several broad definitions. It is alternatively the ability to introspect about one's emotions and thoughts, the ability to distinguish oneself from others, and the representation of oneself as a being. Operationalizing these definitions into objective measures that can be tested scientifically is tricky, and it has not been clear that efforts to do so even converge on the same topic. Nevertheless, the desire to understand self-awareness is strong enough that researchers have made a variety of attempts.

## The Evidence We Would Need

The inherently subjective quality of self-awareness creates barriers to objective study. You likely experience self-awareness based on your apparently direct introspection about the activities in your own mind. But you cannot introspect into others' minds and thus cannot know firsthand if others are self-aware. The inherent difficulty in knowing what others experience has aptly been called the “problem of other minds.” Because we cannot know other minds by the same apparently direct means by which we know our own minds, we must rely on several types of indirect evidence. First, neurotypical adults will say they are self-aware. Absent converging supportive evidence, such a report is weaker evidence than it might appear to be at first. We can readily write a computer program that would declare itself self-aware, but we know that would be a fabrication. A drunk or a sleeping person might declare

that they “know what they are doing” even when they clearly do not. Second, one might infer similar cognition from shared phylogeny. Other humans have the same evolutionary history and share the neural mechanisms that produce your cognition and behavior. Thus, they might also share your self-awareness. If another species behaves like it might be self-aware and they are closely related to us, then perhaps the most parsimonious explanation is that they are. However, this assumption ignores the fact that closely related species, and even individuals within a species, can differ dramatically in their cognitive abilities. Third, one may infer the thoughts of others from shared behavior. For example, you eat when you feel hungry, so you may infer that another person who eats is experiencing a subjective state of hunger. But we know that eating also occurs in the absence of feeling hungry. We also know that even complex behavior can often occur without self-awareness. The beginning driver must attend carefully to every use of the blinker and every rule of the road, but an expert driver can arrive safely at the destination without any apparent awareness of the trip.

Because nonhuman animals cannot give verbal self-report, we are left to use a combination of shared behavior and phylogeny to evaluate hypotheses about the degree to which different species are self-aware. To do this, researchers use a constellation of behaviorally testable traits that seem to correspond to self-awareness in humans. The benefits of this approach are that it allows assessment of self-awareness in nonverbal species and that it is solidly based on behaviors from a verbal species, humans, that professes self-awareness. The weaknesses of this approach are that we must assume that nonhuman animals and humans rely on the same cognitive or neural mechanisms to accomplish behavior. Many testing conventions routinely vary between human and nonhuman tasks, such as verbal instructions versus trial-and-error learning, being tested in mother’s arms versus a cage, or having years of explicit schooling versus being naïve. Different species tested in different ways often use different mechanisms to perform the same feat, and researchers must always seriously consider the

degree to which apparent behavioral similarity between humans and nonhumans could be superficial.

## The Evidence We Have

Comparative psychologists have developed several notable approaches with nonhumans to test behaviors that imply self-awareness in humans. Here, we give an overview of the performance of multiple species on tests for three notable capacities related to self-awareness: metacognition, theory of mind, and mirror self-recognition.

### Metacognition

If you have ever second-guessed how you spelled a word and looked it up to double-check yourself, you have engaged in metacognition. Metacognition is colloquially described as thinking about thinking. It encompasses a broad spectrum of cognitive processes involved in the monitoring and control of thinking. Metacognitive behavior can be controlled by multiple cues, both public and private (e.g., Basile et al. 2015; Brown et al. 2017; Hampton 2009). Public cues are those that others can monitor, such as knowing that the person sleeping in class will need to restudy the material later, whereas private cues are those that only the thinker can monitor, such as knowing that you should restudy the class material later because you have forgotten it. Both public and private cues are useful for efficient cognition; however, the ability to metacognitively monitor private cues may uniquely inform our knowledge of self-awareness because self-reflective thought has been proposed to be a key component of self-awareness.

### Basic Metacognition Paradigms

Metacognition paradigms in nonhuman animals rely on a primary task that requires a cognitive judgment and a secondary metacognitive judgment based on the subject’s perceived likelihood of success on the primary task. To elicit metacognitive responding, the primary task usually involves a range of difficulty levels: easy trials on which the subject is likely to answer correctly

and difficult trials on which the subject is likely to answer incorrectly. Secondary metacognitive judgments allow the subject to take some form of adaptive action, such as allowing subjects to opt out of difficult trials, return to difficult trials later, make wagers based on past choices, or seek information when ignorant. Metacognitive responses can occur prospectively before tests, concurrently at the same time as the test, or retrospectively after the primary cognitive test has been completed.

Primary cognitive tests typically require one of two types of judgments: perceptual or mnemonic. Because it is relatively simple for experimenters to manipulate the objective difficulty of psychophysical stimuli, metacognition tasks have often relied on perceptual discriminations. A psychophysical discrimination requires animals to discriminate stimuli that differ along a continuum, with some difficult trials that fall close to the boundary of the just noticeable difference between two anchor stimuli. For example, subjects might discriminate between sparse or dense dot displays (e.g., Smith et al. 2014) or need to identify a target of a specific size or brightness from among distractors (Brown et al. 2017). The second major type of judgment used in metacognitive tests is mnemonic. Memory tests depend on the persistence of a mental representation for a previously seen stimulus through a retention interval. The quality of the memory either varies stochastically or can be experimentally manipulated, so subjects sometimes remember and sometimes forget (e.g., Basile et al. 2015; Hampton 2001). With memory paradigms, subjects make metacognitive judgments about whether they remember or have forgotten the answer.

Different tasks rely differentially on public and private cues. Metacognitive judgments about perceptual stimuli may rely on public cues because the difficulty of the stimuli is externally observable by all, whereas judgments about memory are more likely to be controlled by private cues because the state of your memory is something only you can access. Similarly, prospective judgments may rely more on private cues because the subject must make their judgment without seeing

the choice stimuli and therefore are more likely to rely on internal representations. Thus, in the evidence we describe below, we cover perceptual judgments briefly and concentrate on prospective tests of metamemory.

### Evidence About Metacognition

Most species that have been tested have succeeded at making adaptive metacognitive responses about perceptual tests. These include insects, cetaceans, rodents, birds, old- and new-world nonhuman primates, and humans (the success of this field has yielded more good comparative studies than our citation limit allows; for two good reviews, see Hampton 2009; Smith et al. 2014). Because these perceptual tests can often be based on externally observable public cues, it is difficult to unambiguously interpret them as evidence for a private, introspective self-awareness (Fig. 1).

Compared to metacognitive tests that use perceptual tasks, those that rely on memory for their primary discrimination have given more mixed

**Self-Awareness, Fig. 1** A capuchin crouches to look down a tube in search of hidden food. According to the premise of several metacognition experiments, an introspective animal will search when ignorant but select a tube immediately when knowledgeable. One interpretation of this introspective access is that it is only possible if the animal is self-aware. (Adapted with permission from a photo by Benjamin Basile)

results across different species. Humans, other great apes, and old-world monkeys reliably opt out, seek information, or wager small amounts when their memory is weak (for a recent review, see Smith et al. 2014). Similar evidence from new-world monkeys is equivocal (e.g., Basile et al. 2009; Fujita 2009). A recent paper suggests that rats can opt out of difficult odor memory tests (Templer et al. 2017). Evidence from dogs and pigeons shows that they generally do not behave metacognitively in memory tests (Brauer et al. 2004; Sutton and Shettleworth 2008). The most robust conclusion from these results is that humans, apes, and old-world monkeys seem able to explicitly monitor some aspect of their memories.

One reason memory tests are important is because they provide the unique opportunity to present the metacognitive judgment prospectively, before the test stimuli are seen. Placing the metacognitive discrimination before the test stimuli are visible limits the availability of public cues to control metacognitive judgments, which increases the likelihood that metacognitive judgments are controlled by private cues like introspection of an internal memory state. Large-billed crows have made successful metamemory judgments in retrospective but not prospective paradigms (Goto and Watanabe 2012). In new-world capuchin monkeys, at least one individual was able to make prospective judgments, but the other tested individual could not (Fujita 2009). The recent report of rat metamemory used a “pseudo-prospective” response that is promising and justifies more investigation (Templer et al. 2017). However, only old-world primates, including humans, apes, and old-world monkeys, robustly and repeatedly pass prospective metamemory tests (for a review, see Hampton 2009).

#### Does Metacognition Test Self-Awareness?

The liberal interpretation of observed species differences in metacognitive performance is that they reveal the degree to which different species introspect about their own cognition and thus the degree to which they are self-aware. Specifically, humans, other great apes, and old-world monkeys robustly “succeed” on prospective metamemory

tests and thus are most likely to share an introspective self-awareness. The successes and failures in perceptual or non-prospective metacognitive tests are harder to interpret with respect to introspection, but even they could possibly indicate some level of self-awareness. Humans and nonhumans alike use a variety of cues to make metacognitive judgments, based on what information is salient and available under given testing conditions. For example, although public cues are available in perceptual tests, multiple studies have shown that some species, such as rhesus monkeys, generalize performance across a variety of metacognitive tasks (e.g., Brown et al. 2017). Generalization suggests that their metacognitive judgments may be controlled by a domain-general cue, such as private introspection about uncertainty, even on perceptual tests.

The skeptical interpretation of these metacognitive tests is that the ability to make metacognitive judgments does not necessitate self-awareness. If a metacognitive task relies on judgments about public cues, then it is difficult to strongly infer any introspection. For example, a pigeon completing a psychophysical brightness discrimination could learn that certain brightness levels, those near a perceptual threshold, are rarely rewarded. The pigeons might then naturally avoid these low-reward trials if given the option. Importantly for any interpretation relating to self-awareness, this behavior would be a cognitive judgment of the reward contingencies in the external environment and would not involve any introspection involving a subjective sense of self. Thus, the skeptical interpretation of perceptual metacognitive tests is that they measure learning about the relations between reward probabilities and environmental cues.

Even tests of metacognition that likely preclude the use of public cues, such as prospective memory judgments, may not test self-awareness. Although introspection may involve self-awareness, it does not always need to do so. For example, a vending machine monitors what is inside itself and will opt out of transactions it cannot complete, but it does not have human-like self-awareness. Researchers of human

metacognition make the distinction between noetic metacognition, judgments based on an explicit cognitive representation, and autonoetic metacognition, judgments based on a self-referential state that would relate to self-awareness (Metcalfé and Son 2012). Thus, a monkey faced with a prospective metamemory judgment may noetically know “the answer is stimulus X” but still not autonoetically think “I am certain that the answer is stimulus X.” Metamemory judgments may reveal which cognitive processes are subject to explicit monitoring in a given species without necessitating that the subject is thinking about itself.

#### Metacognition Summary

Many species make metacognitive judgments, but the interpretation of that performance changes substantially depending on specific task parameters. Prospective judgments of memory provide the strongest evidence for explicit introspection and thus hold the most relevance for self-awareness. Most species are able to make judgments about public cues, such as with concurrent perceptual discriminations, but generally only old-world primates show robust evidence for making decisions about private cues, as with prospective mnemonic judgments. The liberal interpretation of this evidence is that old-world primates, including humans, other great apes, and old-world monkeys, all possess an introspective self-awareness. The skeptical interpretation of this evidence is that metamemory tests indicate which cognitive processes are explicitly monitorable, but such monitoring does not necessitate self-awareness. Nevertheless, these studies provide information about what cognitive processes are explicit or implicit in different species.

#### Theory of Mind

In poker, you might bluff by betting a lot even though your cards are terrible. Bluffing relies on a player’s ability to know that different players know different things, to predict another’s behavior based on their unique knowledge, and to influence that behavior by deceptively giving incorrect information. This ability to know that knowledge states control behavior and that your knowledge

states are different from those of others is called theory of mind.

#### Basic Theory of Mind Paradigms

Most theory of mind tests are variations on a false belief task. In human developmental work, the most well-known false belief task is the Sally-Anne test (Baron-Cohen et al. 1985). In the Sally-Anne test, an experimenter shows the child subject that a desired object is in one of two hiding places. Then, the first experimenter leaves the room, and a second experimenter arrives to move the object to the other location. The child is then asked where the object is and where the first experimenter will look for the object when they return. The first question tests whether the child understands that the object has been displaced. The second question tests whether the child understands that the behavior of the first experimenter will be controlled by their now out-of-date knowledge about the location of the object. If the child expects the experimenter to search where the experimenter saw the object previously, it is taken as evidence that the child attributes a “false belief” to the experimenter and thus that the child has theory of mind.

Most paradigms used with nonhuman animals have borrowed their logic from the Sally-Anne test. In general, the subject is presented with a desired and hidden object, usually food, and another individual that is either ignorant or knowledgeable of the hiding location. Different studies have used either a conspecific or a human experimenter as the other individual. If the subject behaves differently in the presence of a knowledgeable partner than in the presence of an ignorant partner, then an argument can be made that the subject attributes the respective knowledge state to their partner.

Additional evidence for theory of mind comes from anecdotal observations that might be attributable to deception or audience effects. Deception involves the act of hiding information, or giving incorrect information, to others. For example, a poker player may act nonchalant after receiving a good hand, or a chimpanzee might not give its usual food call upon finding desired food. Audience effects refer to when an individual behaves

differently when in the presence of other individuals than when alone. For example, a poker player may bluff only when playing against another individual and not when playing on a poker machine, or a monkey may give a predator alarm call only in the presence of other monkeys. Both deception and audience effects have been taken as implying that subjects attribute mental states to others.

### Evidence About Theory of Mind

Many species produce natural behaviors that seem deceptive or vary as a function of audience presence. Chimpanzees have been observed to walk in the opposite direction of highly prized food when in the presence of other chimpanzees (Hirata and Matsuzawa 2001). This could be interpreted as reflecting intentional deception. Marsh harriers have been reported to begin courtship routines but then terminate those routines when they had gained access to the mate's food cache (Simmons 1992). Similar behaviors have been observed in a variety of species.

In studies based on human false belief tests, a variety of evidence has been gathered in great apes. Chimpanzees will attempt to retrieve food if a dominant conspecific is ignorant of the food's location but will avoid retrieving the food if the conspecific knows the food's location (Hare et al. 2001). This might indicate that they attribute a knowledge state to the conspecific. In a recent study using eye tracking, chimpanzees, bonobos, and orangutans watched a human chase a costumed human into a straw pile but then watched the costumed human dart to the opposite straw pile while the first human wasn't watching (Krupenye et al. 2016). When the first human returned to search the two piles, the apes looked at the first pile in anticipation, as if predicting that the human would search in the wrong location because he held a false belief.

Related studies have looked at the ability of subjects to retrieve food based on the indications of knowledgeable or ignorant partners. In some studies, chimpanzees spontaneously use human or conspecific signals to choose among potential locations of hidden food (Itakura et al. 1999). In contrast, monkeys such as capuchins generally learn to follow similar signals only after trial-

and-error training (Essler et al. 2017). These species differences suggest that some species, like chimpanzees, spontaneously attribute knowledge states to others, whereas other species, like capuchin monkeys, may only do so under limited circumstances. Similar studies have been done with food-caching birds. Jays will preferentially cache food behind opaque barriers compared to transparent barriers when in the presence of conspecifics (reviewed in Clayton and Emery 2015). In addition, if they were observed by another bird, they would later re-cache the food in a different location. Importantly, this re-caching was dependent on whether they had previously pilfered another bird's cache. This suggests that they infer the knowledge state of other birds by simulating what their own knowledge state would be in that situation (i.e., I would pilfer this site if I were him, so I'll re-hide it somewhere he hasn't seen) (Fig. 2).

### Does Theory of Mind Test Self-Awareness?

The liberal interpretation of theory of mind tests is that "passing" them is only possible if the subject is self-aware. If you attribute a mind to me and know that I believe something different than you, then you must also be attributing a mind to yourself, one that believes something different from me. This knowledge of your mind as a unique mind among many is, for some, the very definition of self-awareness.

There are several skeptical interpretations of theory of mind tests. The most lasting criticism of theory of mind tests is that they are non-mentalistic "theory of behavior" tests (e.g., Heyes 1998). You can probably predict with some accuracy the behavior of a poker machine, but you likely don't attribute a mind to that machine. Further, your ability to predict a poker machine's behavior says nothing about your own self-awareness. Similarly, it is possible that a chimpanzee who predicts that a conspecific will retrieve visible food or a bird that re-hides its food cache may be predicting another's behavior without representing another's mind or another's false belief. Thus, a plausible explanation for putative theory of mind studies in chimpanzees, for example, may be that they have learned to predict the

**Self-Awareness, Fig. 2** A western scrub jay caches food while a conspecific watches. According to the premise of several theory of mind experiments, an animal that attributes mental states to others will avoid thievery by changing the location of its caches when the conspecific

is no longer present. One interpretation of attributing minds to others is that it requires being self-aware of one's own mind. Illustration based on description of experiments reviewed in Clayton and Emery 2015

behavior of conspecifics under given circumstances, without necessarily attributing a mind to them. One intermediate explanation, proposed specifically for chimpanzees, is that they attribute limited mental capacities to others, such as intentions and knowledge states, but not other mental capacities, such as false beliefs (Call and Tomasello 2008). Whether a limited but present theory of mind implies a limited but present self-awareness is unclear.

Even in studies of humans, for whom we generally assume self-awareness, the discriminative validity of theory of mind paradigms has been questioned. In studies of human children, there are country-to-country differences in the age at which human children begin to “pass” the false belief test. For example, at 44 months of age, roughly 40% of Japanese children “pass,” whereas nearly 70% of Australian children “pass” (Wellman et al. 2001). These differences are better explained by other factors, such as variability in inhibitory control due to cultural differences in parenting style, rather than by positing that Australian children are more self-aware than Japanese children. Consistent with this, a wide variety of relatively minor task parameters, such as how the question is asked or if the actors are live humans or puppets, significantly change

whether children “succeed.” The susceptibility of theory of mind tests to changes in relatively minor task parameters, even in a species to which we regularly attribute theory of mind, makes the success or failure of an individual subject or even an entire group in an individual study difficult to interpret.

Much of the evidence relying on anecdotal observations cannot be unambiguously attributed to theory of mind. Seemingly deceptive behavior can be exhibited as a result of operant learning of external behavior-reward contingencies (omitting food calls in the presence of others results in more food and is thus repeated), happenstance (a potentially deceptive behavior of initiating mating to gain access to the mate's food could result from a legitimate mating display being abandoned once desired food is visible), or species-typical behavioral patterns. For example, clear demonstrations of deception and audience effects are exemplified by behaviors that are sometimes considered fixed action patterns. Fixed action patterns are highly stereotyped reflexive behavior sequences. Consider the broken-wing display given by several bird species (see also similar behaviors in fish), in which a parent bird will walk away from its nest in a hobbling fashion that resembles a bird with a broken wing. The

behavior has the outward appearance of being intended to deceive a predator and is only performed when a predator is present. Nonetheless, the behavior is highly stereotyped, reliably elicited by the correct stimuli and circumstances, and exhibited without training in several species. The varying explanations for such observations make it difficult to attribute them to intentional deception or theory of mind.

### Theory of Mind Summary

Studies of theory of mind in nonhuman animals come primarily from observational anecdotes of seemingly deceptive behavior or from experiments based on human false belief tests. Several species, such as chimpanzees and some bird species, seem to engage in deceptive or audience-dependent behaviors in the wild and discriminate between knowledgeable and ignorant partners in false belief-like tests. The generous interpretation of these tests is that these species attribute independent minds to others and thus are likely aware of others' minds and their own minds. The skeptical interpretation of these studies is that the observational anecdotes can be attributed to a variety of non-theory of mind causes, that theory of mind tests are poor at actually discriminating those who have theory of mind from those who do not because "failure" can be attributed to other causes, and that the behavioral prediction seen in nonhuman tests does not necessitate the attribution of minds.

Regardless of the ability of these studies to address questions about self-awareness, they have revealed a variety of interesting behaviors and cognitive capacities. Several species behave in seemingly deceptive ways, and these behaviors may be elicited via different mechanisms. Some species seem to reliably predict others' behaviors. It is likely that similar future studies will produce interesting insights into comparative cognition.

### Mirror-Guided Behavior

Look in a mirror and you're probably reflecting on yourself both literally and figuratively. Because we so often react to mirrors with self-reflection, researchers who are interested in self-awareness in animals have long wondered: What do they see

in the mirror? If they see themselves, then maybe they're self-aware.

### Basic Mirror-Guided Behavior Paradigms

The basic paradigms of studying mirror-guided behavior in nonhuman animals generally fall into three broad categories: (1) studies of the ability to understand the optics of mirrors, as evidenced by the ability to use them as tools, (2) qualitative observations of self-directed behavior elicited by the presence of a mirror, and (3) evaluating whether individuals "pass" the mark test by touching a visual mark on their body that they could not have seen without the mirror.

Studies of the ability to understand the optics of mirrors usually involve requiring individuals to use the mirror as a tool to interact with the world. For example, imagine a rhesus monkey wants to retrieve a piece of food but cannot see the food's location due to a visual barrier. Using the sight of its arm in a mirror, it can correctly find the food. Using a mirror as a tool to see around corners does not in itself test any aspect of self-awareness. However, understanding that mirrors reflect the world is a prerequisite for recognizing oneself in the mirror. Most animals do not live in environments with access to mirrors, or with access only to surfaces that provide blurry reflections, so we cannot assume they would even be able to learn or understand the visual properties of mirrors. The ability to use a mirror as a tool suggests that they do.

Qualitative observations of mirror-guided behavior encompass a broad array of possible types of evidence. In these observations, there is no universally agreed upon litmus test for what "counts" as evidence in favor of self-awareness. Put an individual in front of a mirror and describe its reaction. If that reaction seems largely self-directed, such as using the mirror to look at parts of the body that are usually visually inaccessible, then perhaps the individual recognizes itself in the mirror. If the individual behaves as though its reflection is a conspecific, such as trying to fight it, or if it ignores its own reflection, then perhaps the individual does not see itself.

The mark test is a special type of experiment in which the experimenter imposes a strict pass/fail criterion for self-directed behavior. Typically, a mark is placed somewhere in the individual's body where it cannot be seen without the help of a mirror, such as a dab of dye on the ear. The critical test is whether the individual touches or tried to remove that mark. To "pass" the mark test, individuals should touch the mark more in the presence of the mirror than in the absence of the mirror. This controls for non-mirror-related touching due to the mark being itchy or the individual naturally liking to scratch its ear. For many years, the mark test has been the de facto pass/fail test of mirror self-recognition.

#### Evidence About Mirror-Guided Behavior

What makes studies using mirrors particularly fascinating to researchers of comparative cognition is that species display a wide variety of different patterns of behavior in front of mirrors. Betta fish will "fight," and anole lizards will perform dominance displays to scare off their mirror image. For these species, these displays stay fairly consistent across exposures. The animals seem to never learn that their reflection is not an enemy and thus treat what they see in the mirror as another individual, rather than a reflection of themselves.

Some species, like most species of monkeys, show a different pattern. They do not fight with their reflections, or if they do, they quickly learn that it is not another monkey (de Waal et al. 2005). They can learn to use mirrors as tools to locate and retrieve food (Anderson and Gallup 2011). Mirrors are also routinely used as enrichment devices, and monkeys will use them to peer around corners. Thus, they likely understand the optics of the mirror to some degree. Nonetheless, monkeys do not spontaneously engage in much self-directed behavior, such as using mirrors to examine their mouths or perineae (Anderson and Gallup 2011). Despite numerous investigations, most monkeys "fail" the mark test (but see Chang et al. 2017). Similar results, being able to use a mirror but not engaging in mirror-guided self-exploration, have been reported in parrots (Pepperberg et al. 1995). In one interesting example that combines theory

**Self-Awareness, Fig. 3** A Clark's nutcracker looks in the mirror after an experimenter has surreptitiously placed a mark on its chest. According to the premise of the mirror mark test, an animal that recognizes itself in a mirror will use its reflection to examine the mark on its own body. One interpretation of mirror self-recognition is that it requires self-awareness. (Adapted from Clary and Kelly 2016, distributed under the terms of the Creative Commons CC BY license)

of mind tests with mirror tests, Clark's nutcrackers treated blurry reflections as themselves, pecking a mark and caching normally, but treated clear reflections like another bird, avoiding caching and not pecking the mark (Clary and Kelly 2016). This may represent a limited mirror self-recognition based on broad contingent motion but not extending to fine-grained visual features (Fig. 3).

Finally, a select group of species, most notably chimpanzees, produces a pattern of behaviors that is strikingly similar to that of humans (Anderson and Gallup 2011). They do not treat the mirror as another animal. They can use the mirror as a tool. They often spontaneously use the mirror to explore difficult-to-see body areas. They often "pass" the mark test.

This variety in how different species react to mirrors suggests a possible continuum of mirror self-recognition. On one end, species like fighting fish appear to not understand mirrors or recognize themselves. In the middle, species like monkeys appear to not recognize themselves in mirrors, despite understanding how mirrors work and not treating the mirror image as a stranger. On the other end, species like chimpanzees appear to fully recognize themselves in the mirror. However, species that "pass" the mark test do not

cluster along only a single phylogenetic branch. In addition to humans and chimpanzees, dolphins, elephants, and magpies have been reported to “pass” the mark test. These cases may result from convergent evolution of cognitive processes.

#### Does Mirror-Guided Behavior Test Self-Awareness?

The liberal interpretation of mirror-related studies, especially the mark test, is that they assess self-awareness. Further, that they demonstrate a species continuum revealing both the evolutionary origins of human self-awareness, as seen in chimpanzees, and cases of convergent cognitive evolution, as seen in dolphins. Perhaps more than any other paradigm, the link between recognizing oneself in the mirror and self-awareness is intuitive. A person who looks in the mirror and says “That’s me!” is explicitly self-aware. It is parsimonious to assume that a chimpanzee who looks in the mirror and touches its own face may be thinking something similar.

The skeptical interpretation of mirror studies is that many “failures” reflect less about self-awareness and more about motivation. There is little doubt that species do differ in their reaction to mirrors. However, it is not always clear how to interpret these differences. For example, pigeons and monkeys typically “fail” the mark test. But if they are trained that touching a visible mark results in food, then they will indeed transfer to touching that mark when they need a mirror to do so (Chang et al. 2017; Epstein et al. 1981). In addition, without any such training, monkeys often fail to show any interest in touching marks on themselves even when those marks are plainly visible without a mirror (Roberts 2011). These types of studies suggest that at least some of the “failures” in the mark test are due to motivation.

In humans, there are cultural differences in the age at which children “pass” the mark test. This is similar to studies of theory of mind (see previous section). For example, at 3 to 4 years old, almost 90% of children from the United States “pass,” whereas roughly 50% of children from Peru and 0% of children from Fiji “pass” (Broesch et al. 2011). These cultural differences are better explained by other factors, such as cultural

norms, rather than by positing that Peruvian children are partially self-aware and Fijian children are not.

In chimpanzees, the nonhuman species that most often and clearly passes the mark test, there are also inconsistencies in the data. Roughly half of chimpanzees “pass” the mark test. In longitudinal data, with the same individuals tested year after year, sometimes individuals that “pass” one year will “fail” the next year (de Veer et al. 2003). It seems unlikely that only half of the individuals in a given species would be self-aware, or that self-awareness takes the occasional year off. It is more reasonable to assume that this variability is due to other factors, such as differences in motivation between individuals or days. If true, then the mark test does not discriminate self-aware species from nonself-aware species but rather the combination of an individual’s ability to understand mirrors and their motivation to touch marks.

#### Mirror-Guided Behavior Summary

Tests of mirror-guided behavior generally test whether species understand the optics of mirrors, whether they spontaneously use mirrors to explore their own bodies, and whether they “pass” the mark test by touching an otherwise out-of-view mark on their body. Results show wide spectrum of interesting species differences from complete non-understanding of mirrors to apparent self-recognition. The generous interpretation of mirror tests is that they assess which individuals or species can recognize themselves and thus are self-awareness. The skeptical interpretation is that they assess understanding of mirrors and motivation to touch marks. Regardless of their applicability to self-awareness, the obvious species differences seen in these studies will likely continue to motivate informative research.

### Unresolved Issues and Future Directions

This entry only scratches the surface of what we know about metacognition, theory of mind, and mirror-guided behavior. In addition, these are only three of the major paradigms that researchers

have used to approach the comparative study of self-awareness. With this in mind, it is worth addressing some of the major unresolved issues and future directions.

First, there is the question of whether self-awareness has any utility or if it is an epiphenomenon. There is no question that some of the paradigms described here tap specific abilities that could be useful. Predicting the behavior of others would be useful for social animals because it allows one to anticipate the actions and reactions of conspecifics that help determine foraging and mating opportunities. Introspection and memory monitoring have utility in cognitive control – the ability to actively change thinking to improve learning and remembering. However, in none of these candidate sub-cases is an organism necessarily any better served by being truly self-aware rather than having the component features. It may be that self-awareness is not a unitary process but the complex interplay of multiple processes, with self-awareness arising epiphenomenally from some combination of them.

It is unclear how to interpret the different patterns of species differences seen in the different paradigms that researchers often use to inform questions of self-awareness. For example, rhesus monkeys robustly “pass” metacognitive tasks, even those relying on the introspective private cues, but generally “fail” or show equivocal evidence on theory of mind and mirror tasks. Complicating interpretation, some species “pass” one version of a paradigm and “fail” another, or “pass” the same study 1 year and “fail” it the next. The possible interpretations of these discrepancies broadly fall into one of these variants: (1) These paradigms test self-awareness but have not yet been sufficiently refined to give valid and robust measures. (2) These paradigms test different aspects of self-awareness and not all species display all aspects. (3) These paradigms do not test self-awareness but rather test other aspects of cognition that vary among species and individuals. One explanation for the cross- and within-species difference is that while self-awareness is a categorical binary, it depends on a range of sub-processes. Self-awareness probably did not emerge as a unitary process fully formed for the

first time in humans. Self-awareness emerges gradually via intermediate stages along a developmental trajectory in humans, and it is likely that this was also the case during evolution. If this is the case, many nonhumans may possess a smattering of cognitive capacities that are prerequisite to self-awareness without a fully formed and human-like subjective sense of self-awareness. Future research will benefit from combining the often-abstract laboratory tests with more naturalistic studies that respect a given species’ ethology. Self-awareness is a human concept, and so it is natural that comparative researchers started by borrowing methods from human psychology. However, this leaves open the possibility that species will “pass” or “fail” these tests as a function of how similar they are to humans in ways that are irrelevant to the question of interest. For example, it makes little sense to test a naked mole rat with a mirror, because they have such poor vision. Similarly, it may make little sense to test a monkey in a mirror-guided mark test, because they often do not care about marks. One of the major challenges for researchers who want to expand the comparative study of self-awareness, or related cognitive capacities, to other species will be to devise tests that make sense for a given species.

One recurring issue that hinders progress in research on self-awareness and related cognitive capacities is finding the proper balance between anthropomorphism, attributing human qualities to nonhumans, and anthropodenial, denying human qualities to nonhumans. It is tempting to think that one’s cat recognizes itself in the mirror but also to dismiss the possibility of pigeon self-awareness as inherently silly. This balance is continually threatened by our human biases and by the reinforcement contingencies of academia that reward demonstrations of “smart animals” with high-profile publications. As with many balances, the truth is likely somewhere in the middle, and continued progress in the comparative psychology of self-awareness will probably rely on not tipping too far in either direction. To the extent that we can formulate clear hypotheses that can be tested objectively, we can avoid both anthropomorphism and anthropodenial.

A challenge for future researchers is to identify factors that can alter these processes. Some of these factors will probably be tied strongly to a species evolutionary niche. For example, we might reasonably expect highly social species to be better than solitary species at predicting the behavior of others. Other factors will probably reflect individual experience. For example, most human children experience years of daily mirror exposure and explicit instruction (e.g., “Who’s that in the mirror? That’s you!”), and much of this difference might produce the observed cultural differences. Similarly, reliable differences are present between chimpanzees that are enculturated and those that are not, and results from monkeys and pigeons indicate that they can reliably be trained to engage in mirror-guided behavior, both using mirrors as tools and passing the mark test, if motivated by food. Thus, just as identifying the factors that influence performance on these tests in humans has been a major research focus, identifying the factors that influence similar performance in different species will be a major challenge moving forward.

Behavior necessarily depends on the brain, so it is natural to examine the neural correlates of self-awareness to better understand the degree to which nonhumans possess the same capacities. However, using neural evidence to assess the presence or absence of self-awareness in other species is problematic. First, it is unclear, even in adult humans, how best to arrive at a neural signature of self-awareness. Imaging studies usually require a comparison of two conditions, and self-awareness is so automatic in humans that it is unclear how best to compare a self-aware human to a non-self-aware human. Second, even if we had an unambiguous neural signature of self-awareness in humans, it would be unclear how to interpret the presence or absence of a similar signature in nonhumans. Although neural homology should inform theories of comparative cognition, it is not necessary or sufficient to assume shared function. For example, if we use the liberal interpretation of theory of mind studies in food-caching birds, then bird brains are so different from primate brains that they likely perform the same cognitive function using different neural

hardware. Interpreting the lack of a neural signature as a lack of self-awareness would be ignoring convergent brain evolution, and interpreting the presence of such a signature as proof of self-awareness would be modern phrenology. Ultimately, these are psychological phenomena, and we need to understand them on a psychological level before we attempt to identify their neural substrates. Nonetheless, outside of self-awareness, studying the brain bases of metacognition, mirror-guided behavior, and prediction of social actions holds promise for our understanding the neural correlates of those cognitive capacities.

Comparative psychologists have made many clever efforts to understand processes in nonhumans commonly associated with self-awareness in humans. However, self-awareness continues to be a subjective individual experience. Our best evidence for self-awareness in humans is verbal self-report. We will never be able to “ask” nonhumans if they are self-aware in the same way that we can ask other humans. Our challenge is to better state what animals with self-awareness can do that animals without it cannot and design experiments that test whether animals can or cannot do the behaviors that depend on self-awareness.

## Conclusion

Eighty five years ago, Tolman stated that the very question of self-awareness in nonhumans could produce only guesses (1932). Today, there is still no consensus about self-awareness in nonhumans, and there probably will never be.

Researchers have attempted to answer the question by studying a variety of cognitive capacities that seem intuitively related to self-awareness. Three of the most notable are metacognition, theory of mind, and mirror self-recognition. The liberal interpretation of these studies is that some species think about their own minds, attribute minds to others, and recognize themselves in a mirror. Together, these behaviors paint a rich picture of self-awareness in some nonhuman species such as chimpanzees. The skeptical interpretation of these fields is that

some species can use some aspects of their own cognitive states as discriminative cues, can predict the behavior of others in their environment, and understand that mirrors reflect the world and have the motivation to touch marks. Together, these behaviors demonstrate a variety of interesting cognitive capacities, but none that could not be carried out by a non-self-aware robot. The primary impediment to reaching consensus between the liberal and skeptical views of self-awareness is the classic philosophy “problem of other minds,” which describes the fact that we must take the existence of others’ self-awareness on their word. Because nonhumans cannot give us their word, it is likely that the comparative “problem of other species’ minds” is unsolvable.

Regardless of our ability to answer the big question of whether nonhumans possess human-like self-awareness, the pursuit of this question has produced a wealth of answers to smaller, more-tractable questions. Some nonhumans can monitor some aspects of their cognitive states, can predict what others might do, and can use mirrors in self-guided behaviors. Some cannot. This has been useful research and will continue to inform comparative psychology for years to come.

## Self-Decoration in Humans

Decorating the body with objects or pigments is so routine in every contemporary human culture that most people take it for granted (Kuhn et al. 2001). Yet contemporary jewelry, cosmetics, and tattoos have a long history. Body decoration probably began with colors and expanded to objects. To decorate objects or themselves, ancestral humans in Africa used a red-brown pigment called ochre 200,000–300,000 years ago (Barham 2002) and European Neanderthals used another red pigment called hematite 200,000–250,000 years ago (Roebroeks et al. 2012). Thus, body decoration with color is not unique to *Homo sapiens*. Early decorative objects were pendants and necklaces made by piercing and stringing teeth, shells, or bones. The oldest beads used in human self-decoration, found in Skhūl, Israel, are dated to at least 100,000 years old (Vanhaeren et al. 2006). Fossil beads are among the earliest unambiguous evidence that objects were worn to communicate (Kuhn et al. 2001), broadcasting such information as ethnic, social, and personal identity (Hynes 2006). Self-decoration was pivotal in human evolution because it represented the earliest human attempts at art (Morriss-Kay 2010) and new vehicles of communication (Kuhn et al. 2001). An important prerequisite for self-decoration was the loss or great reduction of body hair (Morriss-Kay 2010).

## Object Handling in Animals

Birds and mammals also routinely handle objects to eat, play, groom, defend, or hide themselves (Beck 1980; Bentley-Condit and Smith 2010; Shumaker et al. 2011; Mann and Patterson 2013), yet rarely self-decorate with them. The best example of self-decoration is a free-ranging female chimpanzee who wore a strip of skin from a fresh monkey kill like a necklace for a day, albeit a one-time observation (McGrew and Marchant 1998). Captive elephants twisted vegetation into ropes and rings that they placed on their bodies, behavior that suggested self-decoration but which Chevalier-Skolnikoff and Liska (1993) classified

as ambiguous. Most examples of animals wearing objects are typically interpreted as protection, play, or display. Crabs ward off predators by shielding themselves with stinging anemones (Griffin 1992). Urchins, caddis fly larvae, and decorator crabs camouflage themselves with broken shells (Bekoff 2004). Apes play and protect themselves from rain by draping themselves with plant material (Beck 1980; Weaver pers obs, San Diego Zoo). Adult male hoofstock, such as rutting elk and moose, amplify their antlers with tattered vegetation in intimidation displays (Walther 1980).

## Self-Decoration in Bottlenose Dolphins

Free-ranging bottlenose dolphins, *Tursiops truncatus*, in Florida have a potential form of self-decoration, grass worn splayed across their dorsal fins (Fig. 1a), in their suite of object handling behaviors (Weaver 2012; Fig. 1b–d). Theoretically, this behavior should not occur because dolphins dislike anything touching their bodies they did not attach themselves (Kuczaj et al. 2012), and accidental contact with plant materials in the author's study area (Weaver 2015) elicits immediate shuddering and diving to remove it. Finally, swimming creates vortices on leading edges of fins that immediately remove objects caught there (Fish et al. 2011). Yet grass-wearing does not elicit shuddering, grass is worn across multiple dives, and some episodes are deliberate. These facts suggest that at least some of the 200+ grass-wearing episodes were intentional. Why do it? Weaver and Kuczaj (2016) investigated grass wearing from 965 surveys of Weaver's 6-mile estuarine study area (2006–2013) that yielded 9,551 dolphin sightings and 190 observations of grass wearing among 79 dolphins. Three years of subsequent grass-wearing data (2014–2016 Weaver, unpub. data) reinforced the following findings, which do not establish but do imply that some social situations encourage bottlenose dolphins to wear grass as self-decoration.

Dolphins primarily wear grass when new dolphins join the group, making it object use in a social setting (Weaver and Kuczaj 2016). Grass

**Self-Decoration in Dolphins, Fig. 1** Suite of object handling maneuvers among Boca Ciega bottlenose dolphins (a) grass-wearing behavior; (b) wearing a whelk

egg case on the dorsal fin; (c) wearing a discarded sunglass lens on the melon; (d) rubbing a catfish along shells growing on ship's hull to remove spines

wearing is five times more likely when dolphins are socializing in affiliative and sexual contexts than when traveling, feeding, or resting. Two-thirds of the grass-wearing dolphins have been seen wearing grass up to eight different times. Yet grass-wearing dolphins do not play with grass as toys or use it as tools to feed, protect, or camouflage themselves, and grass wearing is not an obvious consequence of activities near seagrass meadows. Males and females wear grass at comparable rates, contraindicating a gender bias. Females wear grass across reproductive phases, suggesting it is not limited to social receptivity associated with estrus. For example, the mother of a 4-day-old calf wore grass twice as her group tripled in size with new dolphins.

Grass wearing occurs across various social groups: mating pairs, heterosexual and homosexual groups, and during recreational sex. One example in an affiliative context involved four females and a male who wore grass during a protracted convergence that eventually totaled

32 dolphins. One example in an explicitly sexual context involved frequent changes in sexual pairings between one female and six males, during which the female wore grass four different times and four males each wore grass once.

The common thread across all the varied contexts was that dolphins wore grass when forming a new group, the social process of fusion. During fusion events, a new group member wore grass as it converged on an existing group or a dolphin in the existing group wore grass as new group members joined it.

A fusion event changes the social environment. It can increase existing competition for attention from group members. It can certainly change the social dynamics of sexual interaction by intensifying competition over social partners. Fusions may also introduce ambiguity about subsequent interactions that could benefit from communication that clarifies intentions.

Fusion itself is common. But wearing grass is rare and therefore novel. Novelty attracts attention.

Bottlenose dolphins are attracted to novelty (Kuczaj et al. 2006, 2012), selective about who they observe (Kuczaj et al. 2006; Bender et al. 2009), and modify their own behavior to keep it interesting (Kuczaj et al. 2012). As familiar but moderately discrepant behavior, grass wearing potentially functions as stimulus enhancement that increases conspecific interest in the grass-wearing dolphin. This is consistent with dolphins self-decorating with grass to enhance greetings and bids for attention, or to communicate interest in further social intercourse (Weaver and Kuczaj 2016).

The association of fusion, novelty, and potential bids for attention suggests that grass wearing is related to two fundamental bottlenose dolphin features: loss of body hair and kaleidoscopic social shifting created by fission-fusion behavior. But bottlenose dolphins also practice recreational sex. The combination of fission-fusion and recreational sex may have created unique social pressures that selected for an unusual vehicle of communication involving self-decoration as an occasional social lubricant.

Alternatively, increasing evidence argues that chimpanzees, elephants, parrots, corvids, and cetaceans have culture (McGrew 1992; Boesch 1996; Rendell and Whitehead 2001; Kuczaj and Highfill 2005; Whitehead and Rendell 2015). Further research is needed to establish if grass-wearing behavior is specific to bottlenose dolphins in this geographical location that persists over generations and thus constitutes a cultural component of this dolphin community.

## Self-Directed Behavior

Manuel Soler

Departamento de Zoología, Facultad de Ciencias,  
Unidad Asociada Coevolución: Cucus,  
Hospedadores y Bacterias Simbiontes,  
Universidad de Granada, Granada, Spain

Self-directed behavior can be defined broadly as any behavior directed toward the self, such as scratching, grooming, etc. Self-directed behavior has also been studied specifically within the context of identifying the capacity for self-recognition in nonhuman species. The theoretical interest in self-recognition is motivated by the idea that this cognitive ability could imply self-

awareness, which is a higher cognitive function that has been argued to be unique to humans.

In 1970, Gordon Gallup published an influential paper in which he introduced the mark test. Four chimpanzees (*Pan troglodytes*) were surreptitiously “marked” with an odorless red dye on a point on the body that could be seen only with the aid of a mirror (e.g., on the brow). Researchers subsequently observed the chimpanzees’ behavior both in the presence and absence of the mirror. Individuals that “passed” the mark test increased their mirror-directed exploratory behavior, touching the mark on themselves rather than in the mirror. In contrast, in control situations (in the absence of the mirror and when individuals were sham marked such that the mark did not appear in the mirror), individuals did not show self-directed behavior to the mark area (Gallup 1970). Thus, examining differences in self-directed behavior in the presence versus absence of the mirror (or the mark) was pivotal in demonstrating that chimpanzees were capable of mirror-self-recognition.

## Evidence of Self-Recognition in Studied Species

The mark test has been used to examine self-recognition ability in many species, both invertebrates and vertebrates (see below). When individuals are confronted with their mirror reflection, five different results (or a combination of them) can be obtained: (1) Many of them ignore their mirror-image; (2) many respond to the self-image with social behavior, i.e., treating the mirror-image as if it were a conspecific; (3) some show self-directed behavior; (4) some show self-contingency behavior, i.e., the individual moves in front of the mirror as if assessing the relationship between the mirror-image and its own movements; and (5) a few are able to pass the mark test. Mirror-image exploration and self-contingency behaviors are important requirements in order to pass the mark test, but these behaviors do not imply self-recognition. In fact monkeys and three species of corvids (jungle crows (*Corvus macrorhynchos*), jackdaws (*Corvus monedula*), and new Caledonian crows (*Corvus moneduloides*)) present high levels of

interest for the mirror showing both self-directed and self-contingency behaviors, but crucially, they do not use self-directed behaviors for mark inspection or removal to pass the mark test (Soler et al. 2014). Strong evidence of self-recognition would need touching the mark on themselves (i.e., self-directed behaviors) rather than in the mirror, and/or self-directed exploratory behavior to areas of their body that are otherwise invisible in absence of the mirror. However, often the requirements for the acceptance of self-recognition have been relaxed with less importance attached to the occurrence of self-directed behaviors and, even when individuals are deemed capable of recognizing themselves in a mirror based on their performance in the mark tests, conclusions are often contradictory and/or contentious.

By the end of the twentieth century, it was well known that monkeys did not demonstrate the capacity for self-recognition, although they could use a mirror to locate a hidden object (Anderson and Gallup 2015). Therefore, it was thought that self-recognition was restricted to humans, great apes, and some other mammals with relatively large brains and highly evolved social cognition (Prior et al. 2008). However, during the twenty-first century, numerous papers have claimed that many different species even including insects and other invertebrates are able to recognize themselves in the mirror (see below). Nevertheless, solid compelling experimental evidence involving self-directed behaviors has only rarely been provided. Frequently, there are important problems with these studies. For instance, in many cases, they are based on informal observations showing little more than interest and curiosity by mirror reflections like many non-self-recognizing species. In others, the methodology is too rudimentary to conclude anything, the conclusions are based on evidence provided by a single animal, or the study has failed to be replicated (Soler et al. 2014; Gallup and Anderson 2018).

In invertebrates, the possibility of self-recognition has been suggested in two different groups: squids and ants. Cephalopods such as octopus and squids have relatively large brains and highly developed intelligence; thus, it is

worth testing them for self-recognition. Oval squids (*Sepioteuthis lessoniana*) were subjected to the mark test and marked individuals tended to observe and touch the mirror for longer periods of time than sham-marked individuals (Ikeda and Matsumoto 2007). These cases of interest for the mirror and touching the mirror cannot be considered evidence of self-recognition without direct evidence of self-directed, and not mirror-directed, mark touching (Gallup and Anderson 2018). With respect to ants, recently, Cammaerts and Cammaerts (2015) performed the mark test in several individuals of three different species of the genus *Myrmica*. The authors claim that they passed the mark test given that blue-marked ants in front of a mirror started self-cleaning behavior sooner than in control conditions (absence of the mirror or marked with brown paint, which matches natural coloration). These are seemingly clear results showing self-recognition in ants, but they are very surprising in these small-brained insects. However, given the impoverished vision of ants, the initiation of these self-directed behaviors was likely mediated by the different chemical cues provided by the blue and brown dyes used as marks. In fishes, although some previously published papers suggest that some fish species are able to recognize themselves in the mirror, the provided evidence is very weak, because in studies of manta rays and cichlids, the mark test was not always conducted and, when it was made, self-directed behaviors toward the mark were not observed, which means absence of mirror self-recognition (Hotta et al. 2018).

Mark-test experiments have been performed in several species of birds, including parrots and corvids; two groups that have large brains and complex cognitive abilities. In most of these experiments, the subjects did not pass the mark test by showing self-directed behaviours to the mark. However, in two species of corvids (magpies (*Pica pica*) and Clark's nutcrackers (*Nucifraga columbiana*)), apparently strong evidence of self-recognition behavior has been provided, especially in the magpie. Magpies performed self-directed preening behaviors when in front of the mirror to remove the stickers used in the mark test in two cases. In addition, the

individual that showed clearer evidence for mirror use removed the mark in the four additional tests, (each with a different colored mark), including the control black mark (Prior et al. 2008). However, it has been suggested that the use of tactilely perceivable self-adhesive stickers and the impossibility of producing a true sham mark control could have generated these self-directed behaviors to the mark, leading to false-positive results within a small sample size (Soler et al. 2014; Gallup and Anderson 2018).

In addition, there is a characteristic that could be considered typical of self-recognizing species (elephants (*Elephas maximus*), dolphins, and chimpanzees; see below) that does not occur in corvids: habituation. That is, they lose interest in the mark when they realize that it is their behavior that they are observing in the mirror. When this occurs, they stop self-contingent behavior (i.e., rapid left and right or back and forth movements of the head or the whole body in front of the mirror) and begin to explore normally unseen body parts. However, the two corvid species considered to pass the mark test continuously persisted in responding toward their reflection in the mirror, which indicates social behavior paralleling the behavior of corvids (jackdaws and jungle crows) and all other bird species that fail to pass the mark test (Gallup and Anderson 2018). This point is indicative of lack of self-recognition in corvids.

A convincing demonstration of self-recognition in one bird species would have enormous biological and cognitive implications because it would mean that this capacity has evolved independently in birds and hominoids (i.e., humans and apes), which diverged 300 million years ago. However, the problems mentioned above cast doubts about the validity of previous results and, therefore, more replication experimental studies with improved methodology and larger sample sizes will be needed before the existence of self-recognition in one bird species can be widely accepted.

Most studies of mirror-induced self-directed behavior involve mammals, both aquatic and terrestrial. Among aquatic mammals, different species of the family delphinidae could be predicted

to recognize themselves in mirrors because they possess high degrees of encephalization, sophisticated memory, and a complex social life. Indeed, the bottlenose dolphin (*Tursiops truncatus*) is frequently cited as the non-primate species most clearly showing self-recognition based on Reiss and Marino (2001) who reported evidence that two dolphins used mirror reflection to investigate directly unobservable parts of their bodies that had previously been experimentally marked. Based on these results, it was later suggested that two other species of the family delphinidae possess the capacity for self-recognition because experimental subjects displayed contingency checking behaviors in front of the mirror. However, self-directed actions to the mark could not be detected and quantified as dolphins cannot touch the mark. Therefore, conclusions are based only on contingency checking behaviors and what seems to be prolonged observation of marked parts (Reiss and Marino 2001). In the absence of self-directed behaviors, these results are ambiguous and based on subjective interpretations of results, which “fail to rise to the level of definitive evidence” (Gallup and Anderson 2018; p. 17).

Self-recognition has been attributed to several terrestrial mammal species. In some of them, such as dogs, horses, Rhesus monkeys, and siamangs, provided evidence is very weak (Anderson and Gallup 2015; Gallup and Anderson 2018). However, elephants and great apes are usually cited as species that have shown convincing evidence of mirror self-recognition. The elephant study (Plotnik et al. 2006) had the advantage that an unequivocal mark test could be performed given that these animals can make self-directed behaviors by touching their head with their trunks. It was found that one out of three subjects passed the mark test, i.e., this elephant touched with its trunk the visible mark significantly more than the invisible sham-mark located at the other side of its head. However, the fact that two elephants did not pass the mark test and, mainly, that subsequent repetitions of the test in the successful elephant did not reach the same positive results, cast doubts about the existence of self-recognition capacity in elephants (Gallup and Anderson 2018).

With respect to great apes, it is clear that chimpanzees pass the mark test (see above; Gallup 1970) because the pioneering work by Gallup has been replicated several times with similar results (Calhoun and Thompson 1988; Lin et al. 1992). This is also the case for orangutans (*Pongo pygmaeus*), although studies have included smaller sample sizes and fewer replication studies have been performed (Anderson and Gallup 2015). However, like other species, only a subset of tested apes makes self-directed behaviors to the mark. With respect to bonobos (*Pan paniscus*), it has been reported that, in response to mirror images, they use the reflection to investigate normally unseen body parts, and that their behavior is very similar to that exhibited by chimpanzees (Westergaard and Hyatt 1994). Based on these observations it is broadly accepted that bonobos, as well as chimpanzees, are able to recognize themselves in front of the mirror. However, the mark test has not been conducted in this species, which is considered the indispensable requisite for self-recognition to be demonstrated (see above).

Gorillas (*Gorilla gorilla*) deserve special mention because of the mixed and contradictory results with respect to self-recognition capacities (Patterson and Cohn 2006). In several studies, convincing experimental evidence of some individual gorillas passing the mark test has been reported, whereas, in most cases, no signs of self-recognition were observed. However, in some of the individuals that passed the mark test, different types of training were used. These cases should not be considered as positive evidence of self-recognition in gorillas because it is well known that after training of self-directed actions in front of the mirror, not only monkeys, but also pigeons are able to display self-directed behaviors to the mark (Epstein et al. 1981; Uchino and Watanabe 2014; Chang et al. 2017)). Then, in contrast with compelling evidence found in chimpanzees and orangutans, the findings from gorillas are contradictory. However, in their review of self-recognition in primates, Anderson and Gallup (2015) concluded that, given gorillas' phylogenetic closeness to chimpanzees and humans, the basic capacity of self-recognition may be present in some individuals.

## Conclusions

Self-recognition has been unambiguously demonstrated only in chimpanzees and orangutans. This consensus has been established due to these species consistently making self-directed behaviors to the mark when in the presence of a mirror. Despite claims to the contrary, compelling evidence for self-recognition has not been provided for any other species. These claims have been the consequence of a lack of rigor in two ways. First, claims of self-recognition have at times been made without compelling evidence of self-directed behaviors to the mark in the presence of a mirror during the mark test; and second, in the general scientific basis that confidence in scientific conclusions can be reached only after rigorous replication of previously published studies (Forstmeier et al. 2017). In self-recognition studies, replication is extremely rare and sometimes evidence based on a single individual has been accepted as definitive. Clearly, further well-designed experimental studies are needed to replicate previous findings, particularly studies with a renewed emphasis on evaluating self-directed behaviors to the mark, which have the potential to further elucidate self-recognition capacity in these animals.

## Self-Domestication Hypothesis

Alexander Mackiel

Department of Psychology, State University of New York, New Paltz, New Paltz, NY, USA

## Synonyms

Artificial selection; Domestication; Prosociality

## Definition

Self-domestication is a process by which organisms become domesticated as a product or by-product of natural selection. It is a multi-generational process by which animals become tame, but without human direction. Evidence suggests that self-domestication emerges as a result of selection against aggression, which, in theory, can occur in myriad ways. Like domestication, self-domestication results in a relatively consistent set of phenotypic changes that emerge across species and manifest morphologically, physiologically, behaviorally, and cognitively. This set of phenotypic changes is known as “the domestication syndrome.”

## Introduction

Throughout human history, animals have mostly been domesticated for the purpose of food production and replacing human labor (McHugo et al. 2019). These needs arose with the scaling-up of human societies from smaller hunter-gatherer bands and horticulturist societies to agricultural societies during the Holocene and likely due to environmental and climatic changes associated with warming in this period (Bettinger et al. 2009; Ferrio et al. 2011). The first evidence of domestication appears in the archeological record around 15,000 years ago with the domestication of the wolf, *Canis lupus*, to create “man’s

best friend,” *Canis familiaris*, the domestic dog (Freedman and Wayne 2017).

Since then, humans have domesticated a number of animal species. Pairs of the wild progenitor species and their domesticated variant include: the bezoar ibex, *Capra aegagrus* and the domestic goat, *Capra hircus*; aurochs, *Bos primigenius* and the domestic taurine bull, *Bos taurus*; the wild boar, *Sus scrofa* and the domestic pig, *Sus domesticus*; and the red jungle fowl, *Gallus gallus* and the domestic chicken, *Gallus gallus domesticus* (McHugo et al. 2019).

In the above cases, the domestication process is directed. In other words, humans picked animals with favorable physical characteristics and mated them together to produce offspring that have a greater chance of possessing the desirable parental traits themselves, while selectively eliminating from the breeding pool animals with less desirable traits. This is known as artificial selection. Artificial selection hijacks the power of natural selection, but directs the selection of phenotypic traits that possess heritable variation towards a different end – namely, increasing the probability of animals with traits that are favorable to humans.

However, *self-domestication* is the process of domestication in wildlife but without human direction, resulting from natural changes such as ecological factors (Hare et al. 2012).

For instance, an animal population might experience a change to their feeding ecology that pushes them towards a different mode of foraging that has downstream consequences to their patterns of intergroup conflict. Such a process as this is part of the explanation for the unique evolutionary history of one of humans’ closest great ape relatives, the bonobo (more on this below).

Self-domestication tends to result in a consistent set of phenotypic changes that are seen in other domesticates, which is known as the domestication syndrome (Hare et al. 2012). This is because both self-domestication and domestication likely share many of the same underlying mechanisms, and therefore phenotypic changes that are the result of these mechanisms. Researchers have argued that selection for tameness, friendliness, or prosociality, which can alternatively be understood as selection against aggression, is the primary initiator of

domestication and gives rise to the domestication syndrome (Hare et al. 2012). This is because such a reduction in aggression and fear and greater prosocial feelings towards humans is necessary for successfully breeding animals in captivity (Wilkins et al. 2014). In addition to the animals becoming more tame, friendly, prosocial, and less aggressive through the generations, they also exhibit a host of phenotypic changes that are a by-product of the selection process (Hare et al. 2012). These phenotypic changes serve as a means to identify self-domesticated species in the wild.

Additionally, it is possible for organisms to undergo both self-domestication in the wild and domestication from humans. Hare et al. (2012) describe a two-step process of self-domestication followed by more human-directed domestication in the domestication of wolves to dogs, which serves as a model of how self-domestication might occur more generally in the wild. Because of the relative lack of research on self-domestication per se, this entry will also discuss domestication more broadly, since the former process falls within the latter.

## The Role of Aggression

Researchers have proposed that the constellation of phenotypic changes characteristic of domestication and self-domestication – the domestication syndrome – is a by-product of selection against aggression (Hare et al. 2012). The fact that the main behavioral trait that is consistent across all domesticated animals is reduction in aggression compared to their wild ancestors supports this hypothesis. Domesticated animals have less intra-specific, interspecific, offensive, and defensive aggression compared to their wild ancestors (Hare et al. 2012).

Some of the most convincing work on the connection between domestication and selection against aggression has come from the famous “Siberian fox study” that was initiated by Russian geneticist, Dmitry Belyaev, in 1959 (Belyaev 1979). For this study, Belyaev and colleagues choose as their subjects a species that is

taxonomically close to dogs, but has never been domesticated, the silver fox, *Vulpes vulpes*.

Since the start of this study and up until the present day these foxes have been selectively bred for generations based on a single behavioral criterion – less aggressiveness towards humans. The researchers have also maintained a control group of foxes that are kept in identical conditions as the experimental group except for one difference, they are bred randomly with respect to their aggressiveness towards humans (Belyaev 1979; Hare and Tomasello 2005). In this way the experiment can isolate the effect of one variable – selection against aggression – on the changes they observe.

The researchers have found that by simply selecting less aggressive behavior in foxes and breeding them, over generations the experimental foxes have exhibited a host of phenotypic changes that mirror those of dogs and other domesticated species (Belyaev 1979; Trut 1999). For example, the experimental foxes exhibited tail wagging, floppy ears, barking, and whimpering, along with greater prosociality and tameness (Belyaev 1979; Hare 2018; Trut 1999). This suggests that selection against aggressive behavior specifically is at the basis of the domestication syndrome.

## The Domestication Syndrome

The consistent set of phenotypic changes that is the result of domestication can be put into a few different categories: changes to morphological traits like fur color and patterning, teeth and skull size, and muscularity; changes to physiological traits including the hypothalamic pituitary adrenal (HPA) axis, which regulates the stress response, as well as hormones involved in the stress response like glucocorticoids and adrenocorticotrophic hormone (ACTH); and cognitive and behavioral traits like docility, less aggression, greater social cognition, and prosociality (Hare and Tomasello 2005; Trut 1999; Wilkins et al. 2014; Wilkins 2020). For example, many domesticated animals are piebald, lacking pigmentation on certain parts of their fur, giving rise to the familiar black-and-white-spotted cow commonly

seen in America's Midwest. Additionally, many pig and dog breeds have curly tails and floppy ears, the latter being a trait not seen anywhere else in nature except in elephants (Trut 1999).

Hare et al. (2012) describe other consistent characteristics that are associated with domestication. Domesticates have greater sexual receptivity for more periods of the sexual cycle; morphologically domesticates show reduced sexual dimorphisms, reduced cranial capacity, depigmentation, feminization of skull; and cognitively, domesticates tend to be more sensitive to human social and communicative cues, and show greater skill on cooperative, social tolerance tasks (Hare et al. 2012; Tan and Hare 2013; Trut 1999).

Paedomorphosis, or the retention of juvenile characteristics into adulthood, is one of the most common phenotypic changes characteristic of domestication (Hare et al. 2012). These include changes that are morphological, such as reduced skull size and altered skull shape, and behavioral, such as whining and submissiveness. And they are traits that are present in juvenile wolves but not adult wolves while being maintained in adult dogs (Trut 1999).

What explains the emergence of this common and consistent set of changes that contains very different phenotypic traits across domesticated species? One hypothesis that potentially accounts for most of the phenotypic changes in the domestication syndrome is the neural crest hypothesis (Wilkins et al. 2014; Wilkins 2020). According to this hypothesis, the domestication syndrome is a product of changes to the developmental pathways of an organism. Specifically, domestication acts on the gene regulatory network that gives rise to neural crest cells in embryonic development (Wilkins et al. 2014).

Neural crest cells are a class of stem cells that first appear during early embryogenesis on the dorsal edge of the neural tube, which is the embryonic precursor to the central nervous system. During early development, neural crest cells migrate throughout the body giving rise to the cellular precursors to many different cell and tissue types. Wilkins et al. (2014) explain that the developmental trajectories of the phenotypic traits seen in the domestication syndrome are linked to these

different cell and tissue types that neural crest cells give rise to. Tissues derived from the neural crest cells include much of the skull, peripheral neurons involved in the sympathetic nervous system, the adrenal medulla, which secretes hormones involved in responding to stressful events, pigment-related precursor cells to melanin containing cells, and cells that are precursors to teeth (Wilkins et al. 2014). These characteristics are all altered in domesticated animals and are linked to neural crest cell development.

Specifically, Wilkins et al. (2014) posits that the varied traits involved in the domestication syndrome are products of a reduction in neural cell migration to those specific cellular and tissue areas of the body. For example, many domesticated animals are piebald, depigmented, or possess pigmentation changes on certain parts of their fur. It is known that pigmentation cells (i.e., melanocytes) are derived from neural crest cells, in which case irregular pigmentation is due to the lack of melanocytes in certain areas of vertebrate fur. In this case, it is likely that the irregular pigmentation is a result of reduced neural crest cell migration to these areas (Wilkins et al. 2014). Another example is floppy ears which are a product of insufficient cartilage – a neural crest-derived tissue – in the outer ear (Pendleton et al. 2018). Data from genetic analysis also corroborate the neural crest cell connection to depigmentation and the other traits involved in the domestication syndrome (Pendleton et al. 2018; Qiu et al. 2015; Wilkins et al. 2014).

## Domestication in Dogs

Dogs were the first domesticated animal species (Freedman and Wayne 2017). Before humans played any intentional role in the domestication process, dogs were likely being self-domesticated in response to exploiting the novel ecological niches that humans created. In the two-step model of self-domestication of dogs, Hare et al. (2012) explain that the first step consisted of dogs being self-domesticated in the absence of intentional breeding by humans. In this step, less aggressive dogs likely had a selective advantage compared to more aggressive dogs in hanging around human

settlements, eating their food, and gaining some degree of protection and security compared to being completely in the wild. The first step made possible the second step, which consisted of directed, intentional breeding of dogs by humans to be less aggressive and more prosocial.

Studies show that dogs possess a range of features characteristic of domestication including morphological, physiological, behavioral, and cognitive features (Freedman and Wayne 2017; Hare et al. 2002; Hare and Tomasello 2005). For instance, evidence suggests that dogs possess social-cognitive and social-communicative abilities that are the result of domestication by humans, even relative to animal species with similar cognitive ability (Hare et al. 2002; Hare and Tomasello 2005).

Hare et al. (2002) compared the ability of dogs to use human social cues to identify the location of food to chimpanzees and wolves. Their study design allowed them to assess competing hypotheses for these social cognitive skills in dogs, including that dogs obtained their social-cognitive abilities to make use of human social cues from wolves (i.e., the canid generalization hypothesis), from living with and learning from humans over their life span (i.e., the human exposure hypothesis), or from selection pressure on dogs to acquire social cognitive skills that understand and make use of human communicative cues (i.e., the human domestication hypothesis).

Under different experimental conditions that allowed for the testing of these three competing hypotheses, the researchers only found support for the human domestication hypothesis. Dogs were significantly more skilled than chimpanzees and wolves at following human visual social cues to identify the location of food. Most importantly, their ability to do so did not vary depending on their age or their level of exposure to humans, indicating the role of selection for these social cognitive skills rather than learning over the life span (Hare et al. 2002).

## Domestication in Bonobos

Because of the relative consistency of the correlated phenotypic traits that emerge in species that

underwent selection against aggression, it is possible to infer which species were self-domesticated. This is exactly what Wrangham and Pilbeam (2001) did and Hare et al. (2012) developed more thoroughly to argue that bonobos, our most closely related great ape relative along with chimpanzees, have undergone self-domestication.

Bonobos, *pan paniscus*, are a good animal model to assess self-domestication since more precise comparisons can be made to its undomesticated great ape sister, the chimpanzee, *Pan troglodytes*. Evidence indicates that bonobos speciated from chimpanzees due at least in part to allopatric speciation as a result of the physical barrier of the Congo River, where there is little genetic admixture between the bonobos south of the river and chimpanzees north of the river (Hare and Wrangham 2017).

One of the most striking behavioral differences between bonobos and chimps is their levels of aggression. Chimps are known to be highly aggressive compared to bonobos where encounters of chimps from different tribes are almost always hostile (Hare et al. 2012). While levels of violence and hostility between chimpanzee groups are much higher than within chimpanzee groups, there is still plenty of aggression within chimpanzee groups almost all of which is mediated by males (Wrangham and Peterson 1996).

Chimpanzee societies are organized by dominance hierarchies, which provide a stable albeit somewhat totalitarian social structure that drives many of the incentives for violence (Hare and Wrangham 2017). Dominant chimps bully subordinates and subordinate male chimps bully others below them, who in turn bully female chimps. Additionally chimpanzee males often form coalitions of adolescents that attempt to and often successfully aggress against other chimps especially the dominant chimps in an attempt to oust them from power (Hare et al. 2012; Hare and Wrangham 2017; Wrangham and Peterson 1996).

In contrast to chimpanzees, bonobos are far less aggressive and far more prosocial, which provides initial evidence that bonobos are domesticated relative to chimpanzees (Hare et al. 2012). Field experiments and laboratory experiments

testify to this fact. Laboratory experiments have shown that like humans but unlike chimpanzees, bonobos will share food with other bonobos they do not know (Tan and Hare 2013).

Across four experiments researchers found out the following regarding bonobo prosocial behavior: (1) more times than not the bonobos chose to share food when they could monopolized it, and especially with a stranger, even more so than a groupmate; (2) bonobos will not give up food in their possession if a desirable social interaction is not possible; (3) however, bonobos will also act outside of their self-interest to help another, by exerting effort to help strangers or groupmates acquire out-of-reach food (Tan and Hare 2013). Therefore, this evidence corroborates the self-domestication hypothesis of bonobos since relative to chimpanzees they are much more prosocial and exhibit enhanced social cognition, similar to the difference between domesticated dogs and wolves.

Unlike chimpanzees, bonobos show very little to no aggression towards females, in large part because males do not form coalitions while females do, and they often do so to fight off aggressive males (Hare and Wrangham 2017; Surbeck and Hohmann 2013). Females form the highest ranking members of bonobo society, where no bonobo society has been recorded to have a male or a coalition of males as its highest ranking members (Hare et al. 2012; Hare and Wrangham 2017).

These are striking differences compared to chimpanzee groups in which females bond little with other females and are commonly aggressed against by males. Additionally, chimpanzee groups are ruled by males who violently attack other males in contests for social status in their dominance hierarchy (Hare and Wrangham 2017; Wrangham and Peterson 1996).

Additionally, if bonobos are domesticated via reduction in aggression, they should show developmental delays in their behavior and cognition relative to chimpanzees. In a set of experiments, Wobber et al. (2010) showed that indeed evolution appears to have affected bonobo prosocial behavior and cognition through shaping ontogeny to delay development when it comes to social cognitive and behavioral skills. They assessed

this by looking at behaviors related to food competition, showing that (1) as chimpanzees reached adulthood they became increasingly intolerant of sharing food with another, whereas bonobos retained high levels of juvenile food sharing into adulthood; and (2) relative to chimpanzees, bonobos showed developmental delays in the acquisition of social inhibition (Wobber et al. 2010). Therefore, this research supports the hypothesis that bonobos show developmental delays in cognitive and behavioral traits relative to chimpanzees that are consistent with domestication.

## Conclusion

Self-domestication is a very interesting and still under-researched phenomenon. It is a topic that highlights the need for more evolutionary researchers to assess and specifically look for by-products rather than just targets of selection. If something that results in as complicated of a set of phenotypic changes as selection against aggression does, one really begins to wonder what other similar processes have and are continuing to occur in nature unbeknownst to many researchers. This especially could be the case when considering animal populations that have experienced habitat destruction, shifts in feeding ecology, natural disasters, and maybe even climate change. Such fundamental changes to animal populations would likely result in new selection pressures that give rise – either directly as a product or as by-products of selection – to phenotypic changes that come to characterize the population.

Additionally, these changes can result in very different behaviors and patterns of social structure from the ancestral population that cannot be understood without accounting for these ecological factors. Recently, researchers have begun analyzing human evolution in the light of self-domestication, finding evidence that like bonobos, humans have a number of phenotypic traits that are evidence of *Homo sapiens* being domesticated variants of earlier human species (Hare 2017; Wrangham 2019). These traits include reduced skull, brain, and teeth size, reduced sexual dimorphism, greater prosociality, and less

reactive aggression, among others (Hare 2017; Wrangham 2019). Therefore, in addition to providing a powerful lens through which we can understand behavior and cognition in nonhuman animals, self-domestication might also provide a crucial piece to the puzzle of the evolution of modern humans.

## Self-Injurious Behavior

Khyati Zala  
Hofstra University, New York, NY, USA

## Synonyms

Deliberate self-harm; Self-injury; Self-mutilation

## Definition

Self-injurious behavior (SIB) encompasses the act of intentional harm to one's body that can result in or have the capacity to cause organ or tissue damage (Sigafos et al. 2014). Self-injurious behavior consists of a series of repetitive responses that often has no obvious reinforcer (Tate and Baroff 1966). Self-injurious behavior does not account for various ritualized cultural practices like ear piercing. SIB can vary in severity and can be put in a spectrum depending on the extent of injury (House and Cercone-Keeney 2004). SIB is utilized by individuals to temporarily alleviate intense negative emotions. They may also express self-directed anger or may be a notion to seek help from others. Such behaviors may also help avoid suicidal ideation (Klonsky and Muehlenkamp 2007).

## Common Forms of SIB

Examples of SIB can include behaviors like skin picking, head punching/slapping, pica (eating inedible objects), teeth grinding, eye poking, trichotillomania (pulling out hair), self-cutting, self-pinching, lip chewing, nail removal, air swallowing, and self-poking in body openings like the anus and vagina. Among these, head banging is the most commonly found self-injurious behavior (Sigafos et al. 2014). It is imperative to bear in mind that other behaviors may be more common among various subpopulations.

## SIB Classification

SIB can be classified within four categories: stereotypic, major, compulsive, and impulsive.

### Stereotypic SIB

Stereotypic SIB consists of behavior that is highly repetitive, fixed, rhythmic, and monotonous. It is often seen in individuals with autism and various congenital and developmental disorders. SIB behavior in these individuals is often exhibited as head banging, self-hitting, skin

picking, self-biting, and hair pulling (House and Cercone-Keeney 2004). Although pharmacologic treatment is slightly therapeutic for these individuals, behavioral interventions are much more effective in eliminating such behaviors.

### Major SIB

Major SIB includes single episodes of severe or life-threatening SIB. Examples include castration, eye gouging, and limb amputation. Such behaviors often times have significant meaning to the individual. Psychosis due to schizophrenia or a severe mood disorder are often related to major SIB (House and Cercone-Keeney 2004). The most common form of major SIB is genital mutilation; it is found at higher rates in men than in women. Antipsychotics are the recommended therapeutic pharmacologic treatment for major SIB (House and Cercone-Keeney 2004).

### Compulsive SIB

Compulsive SIB consists of repetitive, high-frequency behaviors that can be mild to moderately severe. These behaviors include trichotillomania, skin picking, and nail biting. Individuals find it difficult to resist such behaviors because they decrease tension or anxiety. Nail biting is the most common behavior in the general population and often times decreases in frequency over time. Behavioral treatments are effective in treating compulsive SIB. Medications can be taken simultaneously to therapeutically treat SIB (House and Cercone-Keeney 2004).

### Impulsive SIB

Impulsive SIB includes skin cutting, skin burning, and self-hitting. These behaviors temporarily relieve unbearable distress among individuals. Impulsive SIB is most commonly seen in those with borderline personality disorder. It is also seen in individuals with antisocial personality disorder, eating disorders, dissociative disorders, and post-traumatic stress disorder. Traumatic experiences can also trigger impulsive SIB. Data suggests that women are more likely to engage in impulsive SIB than men. Treatment includes adaptive strategies that replace the impulsive behavior to help cope with pain and emotions associated with

trauma. Dialectical behavior therapy is effective in treating impulsive SIB in those who have borderline personality disorder. There is little data supporting effective pharmacological treatments at this time. (House and Cercone-Keeney 2004).

### SIB in Development

SIB is most commonly seen in adolescence and early adulthood. The age of onset is usually between ages 13 and 14. (Klonsky and Muehlenkamp 2007). SIB can also occur in early development between 2 and 3 years of age (Schroeder et al. 1997). Without proper treatment early in development, improvement of SIB is unlikely. SIB will often increase in severity during childhood and adolescence and will level out in adulthood (Emerson et al. 2001). Treatments for SIB will be likely throughout an individual's life.

### SIB Risk Factors

#### Disabilities

SIB is prevalent among individuals who have intellectual disabilities (Sigafos et al. 2014). Certain intellectual disabilities may increase the risk of SIB, further explaining its prevalence among this population (Holden and Gitlesen 2006; Lowe et al. 2007). SIB is even more prevalent in those individuals with intellectual disabilities as well as in those with autism or a psychological disorder like depression (Matson and LoVullo 2008). The prevalence of SIB increases with severe intellectual disabilities (Schroeder et al. 1997). SIB is seen more frequently in individuals who have severe disabilities in performing activities of daily living, socializing, and communicating (Emerson et al. 2001; Matson et al. 2000; Schroeder et al. 1997).

#### SIB Prevalence

Approximately 4% of adults report a past history of self-injury with up to 1% reporting a severe past history (Klonsky and Muehlenkamp 2007). Higher rates have been found in adolescents and in young adults, with even greater rates amongst

those individuals receiving mental health treatment (Klonsky and Muehlenkamp 2007).

### Gender and Ethnicity

SIB is found at similar rates amongst men and women. The methods of SIB vary between genders. Women are more likely to self-cut whereas men are more likely to self-burn. Caucasian individuals are more likely to have SIB than its non-Caucasian counterparts (Whitlock et al. 2006).

### Why Individuals Engage in SIB

Affect regulation: SIB aid in alleviating intense negative emotion. Anger, anxiety, and frustration are present before initiating SIB, and a sense of calm immediately follows after injury. Self-punishment can also motivate SIB when the individual has low self-esteem. Although not as common, the urge to influence others may motivate SIB. Those engaging in SIB may feel antidissociation. These individuals explain that they often feel very little or nothing at all. By engaging in SIB, they are able to regain their sense of self (Klonsky and Muehlenkamp 2007). Some may use SIB to avoid attempting suicide. Other individuals may use SIB to seek excitement or exhilaration similar to those experienced during sky-diving or bungee jumping. Some individuals may use SIB to create physical boundaries, differentiating the individual from its environment and other people around him or her (Klonsky and Muehlenkamp 2007).

### Impacts of SIB

Treatment is imperative for individuals with SIB due to high risk of injury and health complications. Long-term health consequences can develop by accumulating damaged tissue over time. These individuals also will have increased medication use, isolation, and use of restraints to prevent SIB. Treatment can also be very expensive due to repetitive hospitalizations and medical care. (National Institutes of Health 1989). Negative social implications of SIB include isolation, difficulty assimilating into society, and

maintaining employment. Likewise, there is a considerable strain in relationships between the individual with SIB and his or her parents, educators, and members of the community. This may significantly decrease overall quality of life for the individual with SIB (Rojahn et al. 2008).

### Treatment Options

Effective treatment includes those based on principles of applied behavior analysis (ABA) as well as those based on principles of behavior modification through environment manipulation. ABA treatment involves a two-step approach that uses assessments to identify the operant function of SIB and then implementing a treatment that will directly reduce SIB. Examples of ABA-based treatments include functional communication training (FCT), non-contingent reinforcement (NCR), and function-based extinction (FBE). Behavior modification treatments involve manipulation of the environment through reinforcement and/or punishment schedules without prior identification of SIB variables. Examples of behavior modification treatments include differential reinforcement schedules, punishment procedures, and contingent use of restraints (Scotti et al. 1991). Other treatment options include cognitive behavioral therapy, auditory integration training, sensory integrative therapy, weighted vests, gentle teaching, electroconvulsive therapy, and exercise. Although these treatment options are available, further research is required to determine their effectiveness. A combination of ABA and behavior modification is often recommended for SIB (Sigafos et al. 2014).

Currently, there is no research that supports the use of pharmacologic treatment as an effective treatment independently. However, the use of pharmacologic agents can effectively treat symptoms of mental disorders that are often experienced in those individuals with SIB.

## Synonyms

Benefectance; Egotistical attributions; Self-serving attribution

## Definition

Self-serving bias is a psychological strategy referring to the tendency of people to make internal attributions for positive outcomes and external attributions for negative outcomes.

Heider (1958) first enunciated self-serving bias in his explanation of attributions for ambiguous situations. He claimed that attributions are shaped by “a person’s own needs or wishes” (Heider 1958, p. 118). Thus, self-serving bias refers to somewhat distorted explanations and inaccurate interpretations of the given situation as compared to an objective standard. Two accounts have been defined to explain biases in the service of the self: the cognitive account and the motivational account.

The cognitive account states that self-serving bias is a result of limited cognitive capacity rather than a motivated strategy (Miller and Ross 1975). Accordingly, individuals as naïve scientists strive to use the available information to make accurate attributions, yet the bounds of cognitive functioning lead to erroneous attributions, and somehow those errors are in favor of the self. Specifically, individuals set goals with the expectation to achieve. Thus, a positive outcome fits well with the previous expectation and results in an internal attribution in favor of the self. However, feedback indicating failure is inconsistent with the prior expectation which leads to search for explanations most, if not all, of the time outside of the self. The

reason behind this process is the asymmetry in memory in which positive experiences are much more salient and easier to retrieve compared to negative outcomes (Taylor 1991). As a result, individuals take action with the expectation to succeed based on the biased retrieval of past experience and make an internal attribution when the expectation is met. A similar explanation states that negative outcomes are inconsistent with the self-view or schemas about oneself (Tetlock and Levi 1982). Since individuals perceive themselves as skillful (i.e., decent, moral, and intelligent), explanations for positive outcomes result in internal attributions while negative outcomes lead to external attributions.

Another explanation derived from the cognitive account for self-serving attribution, in line with the previous one, is biased hypothesis testing, especially for negative outcomes. Though individuals behave like scientists to find explanations for their experiences, they are inclined to collect and rely on information that verifies their previous expectations (i.e., confirmation bias). Therefore, any information supporting the previous expectation regarding the self and positive outcomes is weighted more as compared to inconsistent information (Sheppard et al. 2008).

The motivation-driven account states that individuals engage in self-serving attributions to preserve and protect their self-esteem. Thus, self-serving bias is a motivated action that aims to increase global self-worth by taking responsibility for positive outcomes and externalize responsibility for negative ones (Blaine and Crocker 1993). Various explanations have been provided for the relationship between self-esteem and self-serving bias. Wills (1981) asserted that low self-esteem drives individuals to engage in self-serving attributions while Alloy and Abramson (1979) claimed that low self-esteem is associated with the lack of motivation to enhance self-esteem. Campbell and Sedikides (1999) in their meta-analysis defined 14 moderators including self-esteem and outcome expectation. Accordingly, the common theme underlying those moderator variables, which are associated with self-serving attributions, is a threat to the self. Self-threat is defined as any kind of failure experience, and the link between self-threat

and self-serving bias is stable even after controlling for errors in information processing. Furthermore, findings suggest that self-serving bias is universal rather than being exclusively Western (see Mezulis et al. 2004).

Another motivation defined in the motivation-driven account is self-presentation. According to the self-presentation explanation, individuals try to manage impressions about them formed by others. To be liked and approved by social surroundings, individuals claim responsibility for success and disclaim responsibility for failure (Forsyth and Schlenker 1977).

Overall, individuals engage in biased explanations for their success as a result of imperfect cognitive functioning and motivations to bolster self-worth. A body of research supports both explanations, implying that they are operating in tandem.

## Introduction

Semantics, the study of meaning and its communication, has been a perennial focus of linguists and philosophers. Traditionally, interest in

semantics was restricted to meaning in natural human language, although recent decades have seen the emergence of the fields of biosemiotics and zoosemiotics, which investigate the possibility of semantic content in the behaviors of non-human plants and animals. Given the nature of this encyclopedia, the present entry provides a brief overview of traditional semantics before describing biosemiotics and zoosemiotics in some detail, using the honeybee waggle dance as a case study.

## Approaches to Semantics Across Disciplines

Among Western philosophers, interest in semantics can be traced at least to Plato, who expressed concern about the arbitrary nature between words and their meanings in his dialogue *Cratylus*. Throughout the late nineteenth and early twentieth centuries, philosophical semantics was closely related to logic, concerned with the disconnect between what a sentence appeared to mean and what it should mean following logical analysis. (Mathematically, for instance, “ $3 + 2 = 3 + 2$ ” means the same thing as “ $3 + 2 = 5$ ,” but “Clark Kent is Clark Kent” has a different cognitive significance from “Clark Kent is Superman.”) In recent decades, this logical approach to semantics has been extended to computer science, where the semantics of programming languages is an active subfield.

The modern field of linguistics has been concerned with semantics since its inception in the nineteenth century (and soon gave rise to the separate field of semiotics, concerned with the relationship between sign, signified, and signifier outside of linguistic contexts). Although academic linguistics was dominated from the mid-twentieth century onward by meaning-independent universal grammar, linguists throughout this period considered (and continue to consider) how meaning is related to grammar (i.e., syntax) and how lexical items map onto concepts and events. Meanwhile, it is the semantic implications of many well-known linguistic theories that have captured the popular imagination. The Sapir-Whorf hypothesis, for

instance, continues to fascinate because it suggests that translation is a fool’s errand: no word in Japanese means exactly the same thing that “green” means in English. The notion of embodied cognition strikes us as incredible because it asserts that a word’s meaning, at base, is equivalent to the activation of a group of motor neurons.

In psychology, interest in semantics centers around how meaning is implemented in the minds and brains of human beings and has spanned several subfields of the discipline. Developmentalists, for instance, have investigated how children map spoken words to referents in their environment; psycholinguists have sought to describe the mental lexicon and how it interfaces with concepts; and neurolinguists have investigated how meaning is neurally instantiated, using lesion studies and neuroimaging. Moreover, some cognitive psychologists have endeavored to simulate the neural organization of meaning through the construction of computational models.

Notably, scholarship on semantics has been largely preoccupied with meaning and its communication in humans, but forays into nonhuman semantics were made in the mid-twentieth century. Linguist Charles Hockett, a critic of Chomsky and his universal grammar, identified 13 design features of language; all were found in human language, but most were found in at least one other animal communication system (Hockett 1960). For instance, the arbitrariness that concerned Plato is also present in the song of the western meadowlark and gibbon calls, and semanticity is present in the western meadowlark, gibbons, and the waggle dance of the honeybee. Recognition by the linguistic establishment of semanticity in nonhuman animals came early in the twenty-first century, with Hauser, Chomsky, and Fitch’s (2002) concession that, among the components of language, only the capacity for recursion (i.e., linguistic nesting) is unique to humans.

## Biosemiotics and Zoosemiotics

Animals across a broad range of species convey meaning through their communicative behavior.

Some scholars believe that each “animal provides the stimulus for its partner’s response, which in turn provides the stimulus for the next response in the chain, and so on” (Shettleworth 2009). One way to examine humans’ language specialization is to ask how far another species could progress toward language. Without question, animals communicate. Chimpanzees “clutter” to warn of snakes, “rraup” to warn of an eagle, and “chirp” to let the others know that a leopard is nearby. Even insects have complex communication systems. For example, honeybees perform a “dance” to report information about the distance, location, and quality of a pollen source to their hive’s mate. Clearly animals communicate with one another, but are they capable of mastering language? It is fairly obvious that we can withhold the designation “language” from the informational exchanges of genes and bacteria, but scholars are more interested to see nonhuman animals as having languages of their own. Animal communication is likely to be less complex and elaborated than ours, perhaps, but includes the same general class of systems.

Much discussion on animal communicative behavior has sought to analyze it by attributing semantic content to particular signals: such an approach, for instance, characterizes the treatment of vervet monkey alarm calls as “functionally referential.” Some scholars have offered a formal semantics for the signaling behavior of other monkeys. In contrast, a growing trend in the animal behavior literature rejects the attribution of properly semantic content to such signals, arguing that the meaning they convey should be attributed to their pragmatic value in particular contexts.

When we look at the communicative behavior of other species, all of the systems that we find display a somewhat similar character, based on a number of shared properties. A primary feature is that all (nonhuman) animals have limited, fixed sets of discrete messages to convey. These messages constitute a fixed list and one that cannot be expanded by combining elements to form new and different messages to respond to new and different communicative needs. Even in those

cases where the system is learned, of which bird-song is by far the most robust example, the actual system acquired does not go beyond the character of an essentially fixed inventory. Each message in these systems is limited to the here and now, driven by the immediate circumstances of production. The messages reflect the immediate internal state of the organism, and their production is often triggered by measurable internal factors such as hormone levels. For example, in most temperate species of oscine birds, it is the male that defends territory, and thus only male birds sing. When injected with appropriate levels of testosterone, however, female birds can be induced to sing as well.

In general, when we examine the ecologically significant communicative signals of any animal species, we find that evolution has shaped the animal’s biology so as to be particularly effective in the relevant domain. There has long been a tendency to try to treat animal signals as information-bearing symbols like the words of our language, but it seems more productive to see communication as relying on the ability of one animal to interpret the behavior of another in its observed context. Animal signals do not have the character of symbols, comparable to words in a human language, but observers can still derive information from them by taking into account the context in which they are produced.

When animal language research began in the 1960s and 1970s, some critics contended that primates were simply producing learned responses to their trainers’ nonverbal cues rather than demonstrating true language skills (Terrace 1985). Von Uexküll (1992) gives an extended analysis on the science of signs and meaning in living systems and organisms, “We no longer regard animals as mere machines, but as subjects whose essential activity consists of perceiving and acting. We thus unlock the gates that lead to other realms, for all that a subject perceives becomes his perceptual world and all that he does, his effector world. Perceptual and effector worlds together form a closed unit, the *Umwelt*.” In this context, from a semiotics perspective,

Jakob's idea of cognition is based on semiosis, and a biological understanding of living organisms reveals that *body* plays an essential role to conceptualize and visualize the object and event in the environment of the living system. One of the main points of biosemiotics – the semiotics of all living systems – is that semiosis constitutes a basic structure for the functioning of living systems, semiosis is a basic part of the way living systems function, and it is the element of *interpretants* that creates, affects, and constructs the perceptual world of the organism. Hence, the living systems operate and function in signification spheres (Brier 1999), so seen from the lens of biosemiotics it is an essential prerequisite for all cognition and signification in living systems.

### Case Study: The Honeybee Waggle Dance

The movement patterns of honeybee have been intensively studied as a communication system, and waggle dance activity is associated with nest site selection and probability of nectar sources from the hive. Yet, little is known if neurobiological mechanisms support to analyze how dances are “produced” and “interpreted” (Barron and Plath 2017). In European honeybees (*Apis mellifera*), for example, dances are performed in the contexts of foraging and nest site selection, and on a successful return to the hive, they perform highly stereotyped dance movements. For resources more than a few hundred meters away from the nest, the dance can be described as a repeating figure-of-eight movement, typically performed on the “vertical wax frames” within the dark cavity of the comb hanging inside the hive. European honeybees also dance on the “horizontal board” and perform the most lauded and remarkable “waggle run” of the dance, typically at the “junction between the two loops of the figure of eight”; the bee strides and leans forward, vibrates her wings, and rapidly waggles her abdomen. While

“wagging,” the successful forager also makes a sound by “buzzing” her wings, which results into her realigning and encircling by other 1–6 bees, and after several wagging runs, they leave the nest (Dyer 2002). Waggle dance also guides and escorts a “novice forager” to find her first food source either by using the dance “information” or by “following” the waggle dance (Biesmeijer and Seeley 2005). For an experienced forager, a waggle dance serves as a source to *reactivate* and resume her foraging interrupted by either rainstorm or nightfall or a daytime dip in her flowers' nectar (Frisch 1967; Gil and Farina 2002). Finally, an experienced and engaged forager may need to “find a new food source when her old one fades, and when this happens, she can do so either by following a dance (being a recruit) or searching independently, being a scout” (Biesmeijer and Seeley 2005).

Such an amazing organization of colonies and effectively structured coordination of their activities confirms the belief of Benveniste (1953) that the bees possess the means of communicating with one another. Their capacity to tackle collectively with the unforeseen circumstances, waggle run, and their waggle dance to signal the probability of available food resources lead us to suppose that they have a fascinating capacity of exchanging real messages and evoke a certain behavior as a response.

### Conclusion

Semantics is undergoing a paradigm shift. Scholars across disciplines increasingly recognize that, while nonhuman animals are generally not adept at conveying meaning using human codes, other codes exist that are more appropriate to the creatures that use them. Ongoing research in biosemiotics and zoosemiotics will likely continue to reveal meaning in places where it has not been previously perceived, and the definition of semantics may need to be expanded accordingly.

## Definition

Lifestyle enclosing living (or life stages) both in water and on land.

## Origin of Life and Transition from Water to Land

Animal life developed in water and later invaded the land. Primitive land organisms were mostly myriapod-like forms occupying cryptozoic (i.e., low light, stable and cool temperature, high humidity) habitats. Providing complementary oxygen supply to water respiration during periods of oxygen shortage, air-breathing likely evolved in response to the insurgence of large areas of shallow waters provoked by the shift of the continents in the Silurian period, global decline in oxygen levels during the Middle Devonian, and higher metabolic costs due to greater mobility, competition, and predation pressures. In the end of the Devonian period, the so-called tetrapods (modern amphibians, reptiles, birds, and mammals), animals with limbs, supporting the skeleton, and lungs, slowly evolved into walking terrestrial vertebrates from aquatic ancestors, most likely lobe-finned fish. Tetrapods' later explosive radiation involved major structural and

functional innovations, including new locomotion, respiration, and hearing modalities, making tetrapods one of the most successful groups invading land, together with arthropods and mollusks.

## Extant Semi-aquatic Organisms

The definition of purely aquatic or purely terrestrial – and consequently semi-aquatic – species is arduous. Several small organisms, like nematodes, tardigrades, and rotifers, in fact, live in a film of water, and others, like flatworms, ribbon worms, velvet worms, annelids, centipedes, and millipedes, strictly depend on moist habitats and could be therefore considered freshwater organisms. Many insects (e.g., mosquitos, several aquatic macroinvertebrates) lay eggs and hatch in water and may live in water after hatching, as either nymph or larva, before metamorphosing in flying adults. Penguins and pinnipeds, often considered terrestrial, rest on land but feed in the sea. Also, many phyla are highly variable in their water dependence. Crabs exemplifies this particularly well, varying from species more associated to water, such as the interesting bromeliad crab, which raises its young in water-filled bromeliad leaf axils, where it may form family groups and even change the water quality, to terrestrial species that invaded the land in a late adaptive radiation from marine ancestors. Mollusks also include more terrestrial gastropods with lungs and more aquatic ones with gills.

Several extant fish are capable of prolonged periods of activity on land, either to feed, lay eggs, or escape exsiccation, turbulence, or predators, burrowing and even holding territories, like the mudskippers *Periophthalmus*, which spend enough amount of time on land to be victims of mosquitos and even react negatively to submersion (Graham 1997). Amphibians have several morphological, behavioral, and hormonal adaptations to semiterrestrial life. They have permeable skin and need water to lay eggs and to grow in the first stages of their life cycle as larvae with gills, before becoming air-breathing adults with lungs, except some salamanders and frogs that lack lungs

and rely only on their skin. Land poses a problem for gamete transfer and storing, often overcome by internal fertilization, waterproof eggs, and viviparity. Many of these modifications were obtained with the amniotes (reptiles, birds, and mammals), which, contrary to amphibians, do not require water to lay eggs. Amniotes' remarkable adaptations to survive on land include the "amnios," a bubble with fluid and membranes protecting the embryo, and a skin covered with keratin, a waterproof protein minimizing water loss through evaporation. Several reptiles are extremely adapted to aquatic living, including virtually all turtles but Testudinidae, which are aquatic or semi-aquatic and probably descend from an aquatic ancestor, crocodilians, especially *Gavialis*, which rarely leave the water, and many highly aquatic snakes. Like amphibians, the most specialized forms (e.g., aquatic turtles and some snakes) may extract oxygen from water through their skin. Semi-aquatic birds (e.g., penguins, gulls, geese, ducks) and mammals (e.g., beavers, otters, seals, Pyrenean desman, water shrews, water opossum, minks, hippopotami) have varied degrees of water dependence, from species that almost never leave the water, such as penguins and sea otters, to species that are highly comfortable on land, such as minks and river otters. Humans have also been historically tethered to aquatic habitats, for daily drinking needs, and relying heavily on aquatic and semi-aquatic resources (Erlandson 2001).

## Adaptations to Semi-aquatic Living

Air's and water's physical properties are rather different. Thus, organisms regularly moving between aqueous and terrestrial environments (hereafter "semi-aquatic animals") had to evolve several morphological, physiological, ecological, and behavioral adaptations to perform efficiently both on land and in water (see below).

### Anatomy

Semi-aquatic animals had to evolve special morphological adaptations to regularly move in water and on land. They often have streamlined,

hydrodynamic bodies for increased aquatic locomotion. The forelimbs of Phocidae, for instance, are specialized for locomotion on land while during swimming are retracted into axillary hollows, whereas their hind flippers are specialized for swimming. Otters have a less elongate shape than most other mustelids, as well as shortened limbs and webbed toes, and feet muscles regulating interdigital web tension, supporting their underwater propulsion, providing advantages in water, but less on land, where otters are less mobile than most terrestrial mustelids (Estes 1989). The globally threatened, yet poorly researched, Pyrenean desman (*Galemys pyrenaicus*) presents similar anatomical adaptations to semi-aquatic living, like its comparatively large and webbed feet, fringed with rigid hairs augmenting their surface (Fig. 1). The more aquatic sirenians even lost hind limbs, obtaining propulsion mostly through a laterally expanded tail, and penguins have elongate bodies and reduced limbs modified as paddles. Animals foraging underwater also need to avoid water inflow while swallowing and to cope with mechanical pressure, which increases with depth, and thus developed modifications to close ears and nostrils and to swallow under water (e.g., otters and the Pyrenean desman) and structural bone modifications in the ears to protect from pressure changes (e.g., pinnipeds).

The higher density of water compared to air provides significantly more buoyancy and physical support for the skeleton, in turn facilitating animals' locomotory capacity, while on land animals must compensate the lower physical support to their body provided by the air relying on endo- or exoskeleton, limbs, and tucker muscles. Taking advantage of the positive buoyancy provided by the water, aquatic living often led to the evolution of larger body sizes. Pinnipeds and sirenians, for instance, are large, the largest rodents and shrews are aquatic, otters are the largest mustelids, and polar bears evolved larger body mass than terrestrial bears after their secondary invasion of the marine environment. Increasing body size usually enhances diving capacity, particularly in endotherms (Brischoux et al. 2008). On the other side, however, water's higher viscosity provides more resistance to movement. Semi-aquatic mammals provide a particularly interesting example of morphological adaptations to secondary aquatic life balancing trade-offs between buoyancy and diving. They are denser than water, mostly due to air and high lipid content in their lungs and bodies, respectively, which provides considerable buoyancy (a sea otter remains above water even when using stones to open sea urchins), reducing energetic costs of surface swimming and aiding resurfacing, but is disadvantageous for diving.

**Semi-aquatic, Fig. 1** Some of the anatomical adaptations of the Pyrenean desman (*Galemys pyrenaicus*), a globally threatened semi-aquatic mammal restricted to some part of Spain, France, and Portugal, to semi-aquatic

living: webbed feet with fringed hairs (left) and nasal trompe provided with hypertrophic vibrissae and chemo-/mechanosensitive Eimer's organs helping prey detection (right). (Pictures credits by Lorenzo Quaglietta)

To compensate positive buoyancy and reduce diving costs, they evolved increased bone density, similarly to human divers using counterweights and various birds, like penguins, using gastroliths (Fish and Stein 1991). Foraging strategies and variation in water density between marine and freshwater environments (higher in the former) also influence this trade-off. Within the Lutrinae, for example, the more deep forager and marine sea otter have larger lungs and denser bones than the shallower foragers and mostly freshwater river otters (op. cit.).

Light rarefaction and sound transmission also differ in water and on land. Vision and hearing underwater thus required special adaptations, such as mechanisms for aerial and submerged emmetropia (refraction of light to focus on the retina). A unique example of visual adaptation is represented by the duplicated eye of the four-eyed fish (*Anableps anableps*), allowing it to simultaneously see both over- and underwater. Adaptations aiding vision are particularly relevant for semi-aquatic mammals, as one of their most fundamental senses, the olfaction, is intensively used on land but does not function underwater, being often reduced in semi-aquatic organisms. The Pyrenean desman and *Neomys* sp., for instance, have reduced sense of smell (Stephan and Bauchot 1959), and aquatic carnivores have decreased olfactory turbinate areas compared to terrestrial carnivores (Valkenburgh et al. 2011), possibly reflecting adaptations to secondary aquatic living. Vibrissae, hairs specialized for tactile sensing, help animals with prey detection, especially when vision underwater is limited. They are generally more developed in semi-aquatic (e.g., otters, Phocidae, and semi-aquatic insectivores like the aquatic tenrec *Limnogale mergulus*, the Potamogalinae, and the Pyrenean desman) than terrestrial mammals, particularly in species foraging by vibrations detection (e.g., *Aonyx*) than by vision (*Lutra*) (Estes 1989). The Pyrenean desman perceives vibrations also thanks to chemo-/mechanosensitive Eimer's organs present on its stunning nasal trompe (Fig. 1), and the Platypus and several amphibians even developed electrical senses to locate prey under water.

## Physiology

Animals foraging underwater make prolonged apneas and thus have to solve the problem of breath-holding. To cope with aerobic metabolism constraints during diving, semi-aquatic animals developed several strategies, including reduction in heart rate, diversion of oxygenated blood to the heart and brain, elevation of muscle myoglobin concentration, and anaerobic metabolism of glucose providing the energy for diving and tissue maintenance (Scholander 1940). Lowering physiologic consumption, providing high anaerobic capacity, is common in ectotherms, such as reptiles, which, differently to endotherms, are capable of impressive dives independently of their size – even a nonspecialized green iguana may dive for 4.5 h – and may be a preadaptation to aquatic life (Pough 1980).

Osmosis is another major trade-off regulating animal life in water and on land. Freshwater animals are usually subject to osmotic inward water flow and have to excrete water in excess, while several marine organisms tend to lose water and therefore drink water, which leads them to excrete the excess of salts. A classical example of notable osmoregulatory capacity is provided by the nasal gland of the marine iguana (*Amblyrhynchus cristatus*), which is physiologically adapted to excrete salt, being thus able to survive while feeding almost exclusively on intertidal and subtidal marine algae. Similarly, sea otters are able to maintain water balance despite feeding mostly on invertebrates, which are isotonic to the sea, thanks to their larger kidneys compared with other mammals, which allow them processing large amounts of electrolytes.

## Thermoregulation

Maintenance of body temperature different than environment, i.e., thermoregulation, heavily conditions animal life history strategies in water and on land. As water thermal conductivity is higher than that of air, water absorbs more heat from an organism and more rapidly than air. Thermoregulation is therefore easier in air than water, i.e., the latter is a poorer insulant medium, exposing its inhabitants to thermal stress (heat loss). On the other side, however, temperature absolute values

and fluctuations are generally higher on land, and therefore heat loss is also crucial on land. Semi-aquatic endotherms cope with heat loss by increasing their insulation or metabolic heat production and decreasing surface/volume ratio (Scholander et al. 1950). Dense underfur and air layer trapped within it insulate mammals by preventing water penetration to the skin. Although all mammals have fur, semi-aquatic mustelids (e.g., mink and freshwater otters) and more aquatic-obliged mammals (e.g., platypuses and rodents) and carnivores (e.g., pinnipeds, sea otters, and polar bears) have higher underfur densities than terrestrial or less aquatic forms, revealing potential convergence among poorly related taxa in evolutionary fur modifications due to the transition to aquatic living (Estes 1989; Liwanag et al. 2012). Semi-aquatic carnivores, rodents, and insectivorous also have milk with higher content of fat and lower of lactose, compared to terrestrial taxa, possibly reflecting another adaptation to aquatic living (Estes 1989).

On land, on the other hand, semi-aquatic animals must cope with the risk of desiccation. Most invertebrates and amphibians are strictly dependent from water or humidity and evolved various mechanisms to track the best moment of emergence, usually synchronized with water temperature and light conditions, or of active migration from drying waterbodies. Organisms living in more hot climates show even more extreme adaptations to survive desiccation, including resistant eggs/stages, physiological dormancy, burying underground, shifting to shaded habitats or permanent waters, and other behavioral strategies. Particularly interesting is the behavior of some tree and desert frogs, which secrete and wipe lipids over the body and form cocoons of old epidermis, respectively, to increase skin resistance and maintain their water balance at high temperatures. Organisms living in Mediterranean or dammed rivers also evolved strategies to adapt to regular alternations between dry and wet phases, or floods and droughts, like many insects' life history strategies synchronized to avoid floods or droughts and fish behaviors to avoid displacement by floods (Lytle and Poff 2004). The dense fur of semi-aquatic mammals, while providing insulation in water, imposes a cost on land,

potentially leading to heating, especially during intense physical activity. Strictly aquatic sea otters use their enlarged rear flippers to dissipate heat (Estes 1989), while Eurasian otters may recur to behavioral thermoregulation to either limit heat loss or heating, by foraging more intensely in colder waters (Kruuk 2006) or by reducing their activity at higher temperatures in Mediterranean climates (Quaglietta et al. 2018). Penguins, among the most aquatic birds, also have to deal with opposite pressures resulting from semi-aquatic living. Namely, to facilitate energy conservation in water and resistance to heat stress on land, they evolved several morphological adaptations, including thick subdermal fat, dense, waterproof, and streamlined plumage and extensive arteriovenous associations facilitating countercurrent heat exchange and resistance to heat stress, as well as behaviors, including burrow nesting, body-orientation, and evaporative cooling (Frost et al. 1976). Other examples of behavioral thermoregulation in semi-aquatic vertebrates are changes in body postures or huddling, to drop resting metabolic rate at temperatures below the thermoneutral zone (e.g., pinnipeds, marine iguanas, and the *Myocastor coypus*).

University, Budapest, Hungary

## Synonyms

[Age-related decline](#); [Aging](#); [Progressive deterioration](#)

## Definition

Senescence refers to the progressive deterioration of function with increasing age, observable in various traits related to behavior, physiological functions, survival, and reproduction. The process is detectable both on the cellular and organismal level, and involves every major organ systems.

The term senescence is often used interchangeably with aging, although according to some authors, aging refers to the time-dependent accumulative changes (part of the underlying cause), while senescence is either the observable outcome (consequence) of aging or it refers to cellular senescence.

## Introduction

Cellular senescence underlies organismal senescence. In general, cells cease to divide after a finite number of times and may or may not die. The number of senescent cells in tissues rises during

aging. However, certain cell lines can divide infinitely. “Immortal” cells include most cell lines derived from tumors and embryonic germ cells. Senescent cells are characterized by bigger size, more diverse morphotypes, increase in b-galactosidase activity (a lysosomal hydrolase), increase copies of chromosomes (i.e., three or more in humans instead of two), change in several genes’ expression levels, and shortened telomeres (non-coding regions at the tips of chromosomes). Several factors can trigger cell senescence such as O<sub>2</sub>, H<sub>2</sub>O<sub>2</sub>, ethanol, and ionizing radiations. Senescent cells in tissue may impair renewal and homeostasis and decrease organ function.

Organismal senescence is a complex process which is mainly characterized by increased homeostatic imbalance, declining ability to respond to stress and recover, adapt to changes, and the increased risk of aging-associated diseases. While almost every organism age, the rate and onset of aging shows large variation between and within species. During the last century, several theories attempted to explain the phenomenon, with some of them viewing it as a random error, while others ascribing it to being part of a developmental program. Current data supports that senescence is not simply a random accumulation of detrimental mutations across time but an inherent part of the lifespan connected to the development and life history of the organism (Monaghan et al. 2008). Phylogenetically, senescence is a surprisingly ancient process (Warner et al. 2016), already present in the single cell bacteria *Escheria coli* (Nyström 2007).

In general, longer-lived species have a lower resting metabolism per gram body weight than shorter-lived species do, but there are several exceptions, for example, birds live considerably longer than expected for their metabolic rate. Rodents (mouse and rats) have a short lifespan relative to humans (2–3 years), although the naked mole rat (*Heterocephalus glaber*) live up to five times longer (up to 30 years) than expected by size, due to several factors such as enhanced antioxidant defense, lower insulin levels, and fewer aberrant proteins (Azpurua et al. 2013).

## Background

Senescence can refer to numerous processes, usually categorized based on branches of biology. Physiological senescence covers a variety of changes in behavior, survival rates, and reproduction. For example, muscular senescence (atrophy), immunosenescence, and neurodegenerative processes in the sensory and central nervous system all belong to physiological senescence, affect behavior and cognition, and are widely reported to occur in animals.

Behavioral senescence occurs when the age-related changes are detectable via behavioral characteristics. The primary cause behind most of these changes is physiological senescence (i.e., brain aging), as behavior and cognition is tightly connected to the sensorimotor and central nervous system. For example, physiological deterioration is suspected to be the underlying cause of declining predatory performance in case of aging wolves (MacNulty et al. 2009), while decreased memory and learning abilities are related to brain atrophy. In humans, cognitive decline begins in the mid-twenties. Mild changes in orientation might be a normal part of aging, but deficits in orientation is a sign of pathology. Attentional abilities, memory functions, performance on verbal tasks (i.e., word retrieving) also decline with age. Nearly half of people over 85 years of age have dementia, caused by brain diseases or injuries, which impairs daily functioning. Behavioral changes can also influence survival and reproduction.

Actuarial senescence stands for the increase in mortality rate with advancing age. It is characterized by the age at the onset of senescence and the rate of senescence. A large diversity of actuarial senescence patterns can be observed among species. Zoo animals generally outlive their wild counterparts. In some populations, mortality rates cease to increase at late ages, resulting in a mortality plateau. Fast growth, larger early investment in growth, as well as harsh environmental conditions in early life has been correlated with more pronounced actuarial senescence.

Reproductive senescence means decreasing fecundity with increasing age. Sex difference

in reproductive senescence, if present, usually equal to faster senescence in males. Additionally, females of certain species live considerably longer than they can produce offspring, a stage referred to as the post reproductive lifespan. This occurs, for instance, in cetaceans, elephants, and great apes and is thought to be linked to living in social groups with resident females, but the exact evolutionary mechanisms leading to its emergence is still debated (Bonduriansky et al. 2008).

Different phenotypic traits showed asynchronous changes during senescence in wild mammals (Hayward et al. 2015), leading to uncoupling them, for instance, in case of actuarial and reproductive senescence it can lead to the emergence of a long post-reproductive lifespan such as in humans. This idiosyncratic pattern highlights the complexity of senescence, where the unique pattern of a given individual's aging phenotype is the result of the interplay between different (epi) genetic and environmental factors.

As it has been established during the last decade, senescence is common in wild and captive populations living in their natural or restricted environment, across every taxon, within the life expectancies of the species (Nussey et al. 2013). Its widespread presence is explained by life history theories of aging, based on the concepts of antagonistic pleiotropy (certain alleles which are beneficial on early survival or reproduction are favored by natural selection even if they have negative effects on fitness later in life); and the disposable soma (as resources and energy are limited, allocation and distribution between somatic maintenance and reproduction will be adjusted based on the organism's ecological context). In this sense, senescence is the consequence of sexual reproduction and natural selection favoring investment in early reproduction over long-term somatic maintenance (Gaillard and Lemaître 2017).

Senescence can be delayed. Calorie restriction, specific diet, enough sleep, avoidance of chronic stress, and physical exercise increases lifespan in many animal species. Medical intervention is also available for both humans and animals.

## Conclusion

Senescence is currently viewed as the consequence of natural selection, an evolutionary adaptive trait. The adaptation seems to be a tradeoff between early life gains and late life disadvantages. Its nature as an inherent strategy instead of random error is supported by both experimental laboratory and long-term observation data across various taxa. Linked to the organism's life-history, this interconnected system results in mosaic aging, where different phenotypic traits can show different onset and rate of senescence, with overlapping divisions of actuarial, behavioral, physiological, and reproductive senescence.

## Synonyms

[Dishabituation](#); [Habituation effect](#); [Sensitization effect](#); [Sensitization process](#); [The Dual-Process theory](#)

## Definition

*Sensitization* is a term that applies to both an effect and a process. The sensitization effect is observed when repeated exposures to an environmental stimulus elicit an increase in behavioral response. For example, a child visiting the hospital to receive an injection might exhibit sensitization through an increased behavioral response after each pinch of the needle. In contrast, the habituation effect is a decrease in the level of response after repeated stimuli. The sensitization process deals with the underlying neurological mechanisms that drive response increases in the face of repeated stimulation. The effect (either habituation or sensitization) will be the net result of both habituation and sensitization processes, with arousing stimuli more likely to tilt the overall balance toward sensitization. Organisms use

habituation and sensitization to focus priorities by filtering environmental stimuli such as sights, sounds, smells, etc. (Domjan 2015).

According to the Dual-Process Theory of Habituation and Sensitization, sensitization processes occur in the state system, which is the compilation of an organism's nervous system that determines the general propensity to respond to particularly arousing stimuli (Groves and Thompson 1970). This is analogous but not identical to the Dual-Process Theory that involves thoughts derived by implicit and explicit means (Petty and Cacioppo 1986). In the case of the Dual-Process Theory of Habituation and Sensitization, habituation serves to decrease conscious reflection of a stimuli, while sensitization acts to increase conscious awareness of a stimulus (Domjan 2015; Groves and Thompson 1970). In the Dual-Process Theory of thought, the implicit is always unconscious, while explicit thought is fundamentally conscious (Petty and Cacioppo 1986). Although sensitization is an independent process that can occur in relative isolation, both habituation and sensitization processes interact to produce behavioral responses (Groves and Thompson 1970). The state system cannot function as a simple reflex, as habituation can; therefore for sensitization to take place, arousal must be triggered (in some animals this can take the form of an emotional response). Once prompted, any environment or situation with repeated eliciting stimuli can yield the sensitization effect, even the same stimuli that the individual was habituated to previously but occurs now with arousing background "noise" (Shettleworth 2010).

In all cases, the sensitization effect is understood as an increased facilitation of neural impulses in response to repeated exposures of an arousing stimulus (Domjan 2015). In the relatively simple invertebrate system *Aplysia* (Fig. 1), this can manifest as the result of mediation of interneurons that cause increased action potentials to reflex motor neurons in response to repeated stimulation (Hawkins et al. 2006). Sensitization can be divided further into subcategories, such as incentive sensitization and behavioral sensitization (Temple 2016).

**Sensitization, Fig. 1** *Aplysia sp.* Neural circuit implicated in conditioned response (CR). There are multiple pathways that facilitate action potentials by stimuli. Unconditioned stimulus (US) cause a sensory neuron (SN) to fire and travel to the L29 pathway before the motor neuron (MN) finally causing a conditioned response. Sensitization by a conditioned stimuli (CS) fires action potentials directly to motor neurons causing a heightened response. This pathway has a direct route to the motor neuron (MN)

## Incentive Sensitization

The dopaminergic system is responsible for incentive sensitization due to its response to a broad range of stimuli (Leyton and Vezina 2014). Behavioral incentives range from food to preference of sexual partners to drugs. In humans, the sensitization of the dopaminergic system explains the progressive nature of addiction (Temple 2016). Although drug users need higher doses of psychoactive substances to reach the same level of effect due to habituation, the neural system for drug cravings has been shown to become sensitized. In one study, rats preexposed to amphetamine and nicotine self-dosed cocaine at lower levels than rats without preexposure to psychoactive stimulants suggesting dopaminergic release in anticipation of substance effect (Hogger et al. 1992). There is a form of locomotor sensitization that manifests behaviorally in more active

and responsive subjects. This will occur when dopaminergic pathways become more sensitive to excitatory pharmacological stimuli after repeated presentations (Kalivas and Stewart 1991; Temple 2016).

## Behavioral Sensitization (Sensitization Effect)

Sensitization effects are observed as increases in behavioral responses to repeated stimuli that are substantial enough to elicit arousal or fear. While habituation must maintain stimulus consistency for an effect to ensue, sensitization can occur across a broad range of stimuli due to the activation of arousal systems (Domjan 2015). Multiple studies of rodent species demonstrate that subjects presented with unconditioned foot shocks associated with an auditory stimulus show significant sensitization to that sound (Dirks et al. 2001; Sasaki and Hanamoto 2007; Sheets et al. 1988).

Through sensitization, past experiences can shape behavioral or incentive response levels to future invoking stimuli. Post-traumatic stress disorder, PTSD, is a human condition that has been modeled in animals. The condition results from exposure to chronic stressful events or a single traumatic event. PTSD patients exhibit persistent physiological and behavioral symptoms including increased levels of corticosteroids indicative of stress and a sensitized startle response to triggering stimuli. These associations can manifest as a result of a sensitization process. In one study, rats exposed to tail shocks for a longer period of time developed an exaggerated startle response and increased stress hormone levels even after 10 days. Control rats that received fewer shocks did not show this same persistence of startle responses. The authors propose that this is a model of both sensitization and PTSD (Servatius et al. 1995).

Definition

A decision made by a human or nonhuman animal on the basis of incoming sense data processed by perceptual/cognitive systems of the brain.

Introduction

Humans and nonhuman animals alike are able to behave adaptively in their environment in part because their behavior is based on incoming sense data and prior knowledge of the world. Research on sensory judgment in both cases generally falls under the purview of *psychophysics*, which focuses on how changes in a physical stimulus map onto changes in perception. The simplest case occurs when a stimulus changes from “absent” to “present” (or vice versa), but stimulus changes can also occur across any dimension available to the perceptual system of the observing animal. For example, changes to a physical object may be spatial (e.g., length, color), temporal (e.g., duration, tempo), or constitutional (e.g., weight, volume). Animals – human or otherwise – will vary in their ability to detect these changes, and research on sensory judgment is primarily concerned with discovering the critical factors influencing this process.

A *sensory judgment* is made when an observer decides between competing interpretations of a

stimulus and alters their behavior accordingly, either by responding to an experimental probe (e.g., “same” or “different”) or by acting differently in a real-world environment. Sensory data (e.g., light) physically impinges on a sensory apparatus (e.g., cells of the retina) and is transduced from a physical signal into an electrochemical patterns of neuronal firing. These patterns increase in their abstraction away from the sensory signal that further up the nervous system’s hierarchy. In this sense, all sensory judgment is *perceptual and cognitive* rather than purely sensory; that is, judgments about the nature of stimuli occur only after some neural processing beyond the original sensory trace that has occurred. For this reason, research in this field is generally concerned with the relationship between qualities (and quantities) of a physical stimulus (such as light, which changes in *intensity*) and its perceptual analogue (for light, this is perceived *brightness*).

Some stimulus changes are modality-specific; that is, they operate in only one sensory domain. Color is an example of a modality-specific dimension, as it is an emergent property of several physical properties (hue, saturation, intensity) operating only in the visual domain. Other properties on which sensory judgments may be based are shared across modalities. Frequency is an example of a dimension coded in multiple sensory domains. In vision, spatial frequency is a critical variable coded by the primate visual system, as it is useful for representing certain properties of objects and textures. Auditory frequency is similarly important for primate hearing, as it corresponds with the perceptual property of pitch.

Since sensory judgments depend on the nature of the sensory and cognitive system processing incoming sense data, and animals vary significantly in how their brains and minds are organized, a great deal of diversity exists in the animal kingdom. Certain animal models will be more useful for certain questions. For example, cats and primates are often used in visual perception experiments, as they share certain visual capacities with humans.

Animal psychophysics also requires special consideration of how responses will be elicited and measured by the experimenter (Stebbins

2013). In human experiments, subjects can be asked to produce responses. In animal experiments, of course, no such instructions may be given. Instead, animals are typically conditioned to produce responses to easy cases of the experimental stimuli in question, with the difficulty ratcheting up slowly as the animal acquires the conditioned response. For example, take a hypothetical experiment in which primates must estimate line length and decide which of the two lines is longer. One approach to ensuring that the animals respond appropriately would be to condition them over many trials to associate choosing a longer line with a treat or some other unconditioned stimulus. Over time the primate will learn the rule that choosing the longer line will be rewarded. Once this rule is learned, more difficult trials can be slowly introduced, until the line-length discriminations begin approaching the animal threshold for line-length discrimination.

## Theoretical Foundations

As stated above, the research into sensory judgment is centrally concerned with understanding the effects of changes in stimulus quantity, or intensity, on the perceptual system, as well as the decision-making process guiding responses. This concern motivated much research into the concept of thresholds, both *absolute* (the smallest intensity of a stimulus that can be detected against a neutral background) and *change* (the smallest difference that can be detected). Subsequent theory introduced a pivotal role for decision-making processes as well, which is inherent to the signal detection approach to sensory judgment research. Several complementary approaches, described more fully below, are employed toward achieving a fuller understanding of how sensory judgment changes depending on both physical stimulus characteristics and decision-related variables.

## Thresholds and the Just Noticeable Difference

Sensory judgment becomes more difficult as the difference to be detected approaches a subject’s

absolute threshold for that stimulus type. In this context, as noted above, a sensory threshold refers to the least intense stimulus detectable by an observer. Ernst Weber formalized this concept by discussing thresholds in terms of a *just noticeable difference (JND)* or the minimum amount a stimulus must be changed from some baseline level so that it will be detectable by an observer. This “change” can either take the form of a difference between two or more stimuli or may be simply the onset of the stimulus against a blank, neutral background, in which case the absolute threshold is typically being assessed. Calculation of this difference was formally described in a ratio formula that is now called Weber’s law. This formula encapsulates the fact that as the starting intensity of a stimulus increases, the amount of change needed to achieve a JND also increases. It was noted that Weber’s law did not work well near threshold, and so Fechner (Weber’s student) derived his own law from Weber’s, demonstrating that there is a logarithmic relation describing change in perceived and actual stimulus changes. Stevens (1957) later noted that the relationship between physical intensity and perceived magnitude appears to conform to a log-log function and proposed a new formula, now called Steven’s power law that more accurately describes the relationship for most, if not all, stimuli. Note that there is a stimulus-specific exponent term in this formula; each stimulus is thus somewhat unique in how it is coded. Consequently, the mathematical mapping from physical intensity changes to perceptual changes depends on the stimulus change in question and can be expressed by an exponent the value of which depends on the nature of the relation between the two (exponential, logarithmic, linear).

Take again our example of line-length estimation. What controls whether an observer detects the difference in line length is not the absolute size of the difference in length between the lines but rather the ratio of the line’s length to the length of the difference. That is to say, smaller absolute length differences are more detectable when lines are shorter. This ratio in length judgment is essentially linear; that is, the exponent is one. The perception of brightness changes, however, and is described by an exponent less than one, meaning

that as light intensity increases, perceived brightness initially increases rapidly, but as intensity is increased still more, perceived brightness increases much more slowly.

## Estimating Classical Thresholds: Methods

### Threshold Estimation

#### Method of Adjustment

This simple threshold estimation procedure entails having subjects manually adjust stimulus intensity to its minimum detectable level. Often this procedure is performed many times for the same observer, with the difference between the adjusted intensity values corresponding to the answer given on the previous trial. Once an observer has adjusted the value up and down around a specific value for more than a preset criterion number of times, that value is taken as the threshold.

#### Method of Limits

This method is characterized by estimating a subject’s threshold twice and then averaging the two estimates. Subjects are presented with intense (i.e., easily detectable) stimuli or stimulus differences at first, with subsequent stimulus presentations becoming less and less detectable. Once a minimum intensity at which the subject can detect the stimulus is reached, the reverse procedure is performed; subjects are then presented with very weak stimuli or stimulus differences incrementally increasing in intensity until the detection threshold is reached again. Once both of these have been performed, the average of the two intensity thresholds is calculated and deemed the detection threshold.

#### Method of Constant Stimuli

Another way of indexing an observer’s threshold for a given detection task is to randomly present stimuli of varying intensities over a number of trials. Multiple trials at each intensity level must be tested, and these stimulus intensities must span the range from clearly above to clearly below the observer’s threshold. According to this method,

an observer’s detection threshold is the minimum intensity at which the observer’s detection accuracy falls above chance.

Adaptive Staircasing

Modern computing has proffered dynamic solutions to the problem of threshold estimation, including the use of adaptive testing methods capable of dynamically adjusting stimulus intensity based on prior subject responses. The simplest version of this procedure is called “adaptive staircasing.” Staircasing essentially entails presenting the observer with easily detectable, high-intensity stimulus on the first trial and reducing stimulus intensity by some regular intensity increment every time an accurate detection occurs. Once the subject begins encountering trials near their threshold, they begin making errors. Each error committed leads to an increase in intensity, typically by a multiple of the absolute value of the decreases (i.e., the so-called 1-up-N-down procedure). This is now a common means of obtaining a classical threshold in the vision literature.

Signal Detection and the Role of the Observer

The study of sensory judgments soon was made to go beyond simple characterizations of observer accuracy and instead characterizes the interaction between observers’ judgments and the presence of the stimulus (i.e., the signal). Central to this refinement was the transition from casting sensory judgment as a fixed perceptual process to a mutable decision process based both on the nature of the stimulus and the cognitive state of the observer.

In any detection task, a 2 × 2 matrix can be created fully describing the potential interactions between the observer’s belief about the stimulus and the true nature of the stimulus. Each of the four cells of this matrix represents hits, misses, false alarms, and correct rejections.

- Hit** A subject detects the signal, and the signal occurred.
- Miss** A subject does not detect the signal, and the signal occurred.
- False alarm** A subject detects the signal, and the signal is absent.

**Correct rejection** A subject does not detect the signal, and the signal is absent.

|           | Subject’s<br>Yes | Response<br>No    |
|-----------|------------------|-------------------|
| Signal    | Hit              | Miss              |
| No signal | False alarm      | Correct rejection |

The concept of a classical threshold, while less meaningful in signal detection theory (SDT), is similar to the signal detection concept of *sensitivity*. Sensitivity refers to the ability of the observer to detect a given stimulus, but in signal detection theory, this is only one influence. In fact, the threshold concept in SDT would be incomplete if it only included sensitivity; it must also include *response bias*. Bias reflects a set of influences present in an observer at a given time. These influences affect the extent to which an observer is prepared (or willing) to respond “yes” to the question “was the signal present?”, independent of the presence of the signal itself. An example would be a situation in which a driver is operating a vehicle on a foggy road. The driver is aware that there are other cars on the road, and the danger of colliding with one is high. Consequently, the driver is much more likely to begin braking (say “yes”) if anything that might resemble a car appears (e.g., a swirl of fog). Indeed, the driver’s internal state of increased anxiety might cause them to brake for no external reason. Both of these would constitute false alarms, as noted in the table above. This demonstrates the issue; signal detection and signal reporting are separate but related parts of the process, and can be influenced by different things, but both matter in measuring the ability to detect a change. SDT allows the experimenter to measure sensitivity under different bias conditions and to see that sensitivity does not change when an observer’s level of bias is altered. The fact that classical threshold theories cannot account for the effect of bias on threshold measures led theorists to argue that the concept of sensitivity is a better measure of detection than that of a threshold, which in essence assumes that bias is always controlled across experiments so that it does not

change. Regardless, classical threshold measurements, which are described next, are still regarded as highly informative under controlled conditions and are used routinely in many experimental tests. Note, however, that the classical methods generally assume that bias is well-controlled; therefore, thresholds obtained using classical methods may not generalize well to situations where this is not the case.

## Threshold Estimation in Vision

Sensory judgment – like perception more generally – has been studied most extensively in visual processing. The emphasis on vision is due to both the relative importance of this modality and to the ease of studying it; audition, for example, presents problems in terms of stimulus creation and presentation that until recently have been difficult to overcome. Some sensory modalities (touch, olfaction, gustatory) are still quite difficult to test, and relatively few researchers have attempted to address these modalities.

**Line-Length Estimation:** Tests of this ability use a starting standard line length and examine the ability of observers to detect a change in the length of the line. This can be done by providing both the standard line and the changed (or unchanged) line at the same time or by presenting the standard first, removing it, and then presenting either the same line or a line of a different length. This approach requires that the observer remembers the actual line length for a short amount of time.

## Animal Research

### Rodents

Rodents are often used as animal models of human behavior for several reasons, including their relative ease of use and shared mammalian biology (i.e., a highly developed neocortex). Despite their ubiquity as an animal model, they are less suitable for modeling human perception than they are in other domains. This is largely because rodents use very different aspects of the environment to guide their behavior. While

rodents do use vision to navigate their environment (Chen et al. 2013), their spatial vision is weaker than humans by several orders of magnitude (Huberman and Niell 2011) and is oriented toward nocturnal environments, at least in the wild.

However, that is not to say that rodents are incapable of serving as experimental subjects in research about sensory judgment. In fact, owing to their complex neocortex, including parietal (Kolb and Walkey 1987) and frontal (Uylings et al. 2003; Clark et al. 2004) regions that integrate multimodal sensory data to contribute to decision-making, rodents are increasingly used as animal models for processes once thought too complex for probing with rodents (Carandini and Churchland 2013).

### Primates

Research on primates is more difficult and expensive to carry out but provides a deeper and more direct mapping between the animal model and humans. Hubel and Wiesel famously won the 1981 Nobel Prize in physiology and medicine by mapping the neural basis of visual processing in monkeys. They showed convincingly that visual neurons were selective for basic properties such as orientation, contrast, and spatial frequency (see Wurtz 2009 for a modern retelling of the long-term influence of this research). An early analysis of contemporary research by De Valois et al. (1974) reviewed the basic characteristics of macaque vision and established their fit for use as models of human visual processing.

Primate research is often used as the tip of the spear; findings revealed with the more invasive methods are followed by less-invasive probing into human perception. A modern review emphasizes this: Horwitz (2015) notes the strength of macaque models of vision in reviewing his own work on color perception.

## Human Development

As useful as animal models are, they are mainly intended to facilitate greater understanding of human sensation and perception. It is also worth

noting that there is a great deal of overlap between the behavioral experimental methods used with primates and those used with human infants. Both monkeys and infants are nonlinguistic primates incapable of receiving and complying with simple experimental instructions and are otherwise difficult to work with. Human infants, like primates, require the use of either implicit indices of sensory judgment or conditioning paradigms to elicit responses. For example, one might measure differences in looking time at two stimuli to see if infants can tell them apart (e.g., Teller 1979) or condition infants to kick at mobiles when they see a certain stimulus and then switching the stimulus and measuring kicking (Hartshorn and Rovee-Collier 1997).

Children are born with poor visual capabilities and show substantial development across the first few months of life as input from the eyes and maturation of the brain help to shape perception. The use of threshold detection tasks has been useful in characterizing infant and child maturation levels (compared to adult thresholds) in multiple visual stimulus dimensions. Visual acuity (pattern vision) is tested using multiple methods. Braddick, Atkinson, and colleagues have studied multiple aspects of visual development, including contrast sensitivity (the ability to detect the difference between dark and light areas of a stimulus) and visual acuity. This group and others have developed means of testing these abilities using both behavioral and electrophysiological methods. An example of this type of test is from Braddick et al. (2005). They used visually evoked potentials (an EEG signal temporally tied to the presentation of a stimulus) to examine the emergence of orientation sensitivity in infants between 4 and 18 weeks and found that infants showed a detectable response to orientation changes (e.g., flipping between a diagonal left and a diagonal right grating) even at the youngest ages tested. Braddick et al. (2005) also tested directional motion, using an essentially random pattern that moved rapidly from side to side. Here, infants showed essentially no response until about 11 weeks for faster motion and about 9 weeks for slower motion. Note that the stimulus parameters used were such that adults would have found

both types of change extremely easy to detect; this is a demonstration of the first onset of these abilities. For an overview of multiple such studies, see Braddick and Atkinson (2011).

## Experimental Validity

Most research on sensory judgments has occurred in a laboratory setting. Likewise, and deriving both from the nature of this topic and the experimental method itself, most research on sensory judgment also attempts to isolate single perceptual processes or variables rather than study them in realistic or emotion-laden scenarios. Of course, the real-world processing these experiments are meant to index does not occur in this context. Real-world processing is highly integrative, and multiple internal and external cues may be used to guide adaptive behavior.

The more general concern of experimental external validity, or the extent to which a given experimental method is capable of indexing a real-world process, can be raised regarding research on sensory judgment. Take an example from a task about auditory pitch discrimination. A typical human experiment would be conducted in a soundproof room using flat-frequency headphones and a response box. Such a task would be meant to index how “pitch is processed” generally, but by isolating pitch from other auditory variables, the experimenter limits the extent to which those other variables can influence pitch perception in a normative way.

The concern is magnified in comparative research. Take the case of a highly cited study by Beecher et al. (1979), who investigated Japanese macaque’s perception of other monkeys’ vocalizations. Low- and high-pitched versions of two distinct monkey vocalizations (smooth early high coos and smooth late high coos) were presented to listener monkeys over headphones. With some clever experimental manipulations, the researchers were able to make quite strong conclusions about how monkeys represent acoustic and semantic properties of vocalizations. However, those conclusions were drawn from a highly contrived experimental scenario in which monkeys were wearing headphones and vocalizations

otherwise lacked their normative social context. These caveats limit the extent to which the results can be considered ecologically valid.

## Application

Research on sensory judgment has deeply impacted a number of design fields concerned with how humans interface with machines and computers. One such area is human factors' research and human-computer interaction [HCI], respectively. Heads-up displays (HUD), which are typically translucent displays that allow an operator to receive information without moving their head, have been around in military applications for some time and in nonmilitary applications from at least the 1980s. Tests of the ability of an observer to detect and use this information without being distracted from an external focal point (such as through a vehicle window, with the information being displayed on the window) have been examined using the types of judgment/decision-making testing described above, and there is a strong assertion in the literature that attention capture by the display can have both positive and negative (distracting) effects. This is a demonstration of the role that attention plays in sensory judgments and decision-making in ecologically valid (nonexperimental) settings.

## Conclusion

Sensory judgment is a fundamental topic in psychology, both human and comparative. Adaptive behavior is guided by perception, and perception fundamentally depends on judgments (implicit or explicit) made on the basis of sensory data. The field of psychophysics, aimed as it is at unpacking how physical changes map onto perceptual ones, is quite old and methodologically robust. By characterizing sensory judgments in terms of thresholds, and later in terms of both sensitivity and bias, rich mathematical models of various perceptual processes have been produced.

Human psychophysics is quite developed as a field, and animal psychophysical studies are

increasing in their sophistication, despite requiring extra experimental work to elicit meaningful responses. Rodents are easy-to-use but imperfect models, at least for visual psychophysics. Primates are better models but are more difficult to work with. There also exists a great deal of similarity between primate studies and studies of human infancy. Concerns do exist regarding external validity – experiments in sensory judgment require rigorous control of the experimental scenario, which entails a low degree of overlap between real-world sensory and perceptual processing and that which occurs in the laboratory. Despite this, sensory judgment research, and psychophysics in general, has been applied a great deal in industrial and technological application to improve how humans interact with technology.

## Definition

Serendipity is an epistemological term created to design the occurrence of a fortuitous and fortunate discover.

## Introduction

Serendipity is a term that suggests that accidental discoveries could lead to valuable and relevant results. Serendipity moments are usually those in which the outcome of the research has no relation with the path followed to obtain it. This type of accidental discoveries has sometimes led to huge changes in the course of history. For instance, the erroneous trajectory followed by Columbus that eventually brought him to America.

## Origins of Serendipity

Serendipity is a neologism. The word was generated to denominate the unexpected resolution for an unsolved problem. The origin of the term comes from a traditional Persian story called *The Three Princes of Serendip*. It was proposed by the politician Horace Walpole in 1751 (Cannon 1940). In the tale, the three main characters move forward their adventures using their sagacity over accidental discoveries, taking advantage of fortuitous information (Cammann 1967).

## Scientific Serendipities

Several historic examples of serendipity are well known in the scientific field. Archimedes discovered his famous principle when he took a bath and observed how his body moved an equivalent volume of liquid. His “eureka” expression passed to history as an exclamation of discovery.

In psychology, an example of serendipity was the determination of classical conditioning by Ivan Pavlov. From digestive system to learning, Pavlov was a physiologist interested in the digestive system. While investigating the dog’s salivation reaction, Pavlov accidentally observed that dogs salivated without direct stimulation of their glands (Boakes 1984). He realized that dogs

salivated in the presence of a sound that was involuntarily paired with the food that was used to induce salivation. Progressively, the dog associated the innocuous sound with feeding time, and the salivation response was also observed in the presence of sound alone. Later, Pavlov derived his scientific interest to this curious phenomenon founding the basis of classical conditioning, also called Pavlovian conditioning.

## Serendipity: Chance or Reasoning

Serendipity’s phenomena could seem sporadic. However, it has been proposed (Arfini et al. 2018) that the scientific ability to recognize an unexpected event is a relevant piece to solve a problem. Hence, how the researcher fits accidental observations in the general frame of a problem is crucial for a serendipity to become a scientific discovery.

Through this idea, there is a key concept necessary for a fortuitous observation to become a solid discovery. This is the “insight” concept. To have an insight is to experience a sudden reorganization of information that supports a brief resolution of an issue. Wolfgang Köhler was the one who coined insight as this quick reorganization of reasoning in the middle of a difficult problem. Köhler investigated to what extent primates could solve complex problems (Köhler 1925). This author observed that, in the previous seconds before solving a problem, animals seemed absorbed looking at the situation and later solved it quickly and confidently. Köhler called this lucid moment as “insight.”

Following this argument, some authors have tried to explain the factors that arise from the lucky nature of serendipities. Arfini et al. (2018) explained three factors that involve serendipity discoveries: first, it is a fortunate coincidence usually related with the luck stereotype. Secondly, serendipity has a surprising nature, as it is a non-expected event. Finally, serendipities encourage revolutions in the path of science. In that sense, several serendipities have modified paradigms of knowledge in a Kuhn’s point of view (Kuhn 1970). For example, the discovery of penicillin by Fleming was an accidental chance that dramatically changed the medical field forever.

Serendipity is also possible as far as the researchers are able to fit an accidental observation into a general schema of explanations, thus providing the ability to reorganize a solution in a new qualitative level. So, serendipity acts could be described as keys that led to scientific discoveries.

## Serial List Learning

Damian Scarf and Michael Colombo  
Department of Psychology, University of Otago,  
Dunedin, New Zealand

On the week of September 20, 1948, a symposium titled “Cerebral Mechanisms in Behavior” was held at the California Institute of Technology. The symposium focused on the question of how the nervous system controls behavior and was attended by a number of eminent scientists, such

as John von Neumann, Wolfgang Köhler, Karl Lashley, and Heinrich Klüver. Of the papers presented at the symposium, Lashley’s (1951) paper is likely the most influential and enduring (Bruce 1994). Lashley (1951) focused on the problem of explaining how serially organized behaviors are represented and executed. At the time of his address, the dominant theory postulated that all serially organized behaviors were composed of a chain of stimulus-response (S-R) associations. That is, the functional stimulus for a response ( $R_n$ ) is the response to the preceding stimulus ( $R_{n-1}$ ). Lashley (1951) rejected the chaining theory of serial-organized behavior, especially as an explanation for language, and noted that many errors of speech and writing provide evidence that entire sentences are prepared before they are produced. For example, spoonerisms, the transposition of word sounds such as saying “the Lord is a shoving leopard” rather than “the Lord is a loving shepherd,” are common in speech; if the chaining theory of language was correct, spoonerisms would not occur because only a single word in the sentence would be activated at any given time.

Unfortunately, Lashley’s (1951) focus on examples of human behavior meant that his criticisms of chaining theory had relatively little impact on theories of animal behavior. In the late 1970s, however, a novel paradigm was developed that allowed the chaining theory of animal behavior to be tested (Terrace et al. 1977). Terrace et al.’s (1977) simultaneous-chaining paradigm involves presenting subjects with a list consisting of  $n$  number of simultaneously displayed items (Fig. 1). The subject’s task is to respond to each item of the sequence in a prescribed order learnt during training. Several aspects of the paradigm make it difficult for a subject to rely on an S-R chain. First, all of the stimuli are encountered at the same time, making it difficult for a single item to be the discriminative stimulus for a response. Second, the on-screen positions of the items are changed on each trial, thereby preventing the subject from learning a rote motor sequence. Third, beyond responding to the last item correctly, which results in reward, or committing an error, which results in a punishment, a response to the  $n$ th item of a sequence provides no information as

**Serial List Learning, Fig. 1** The typical flow of a correct trial on the 4-item list. Following the inter-trial interval (5 sec), all four items A (B. F. Skinner), B (fruit bowl), C (car), and D (cup of coffee) were presented simultaneously and subjects were rewarded for responding to them in the order  $A \rightarrow B \rightarrow C \rightarrow D$ . With four items on screen, the chance of a correct response to A is 1 in 4 (25%). Given repeat pecks to a correct item were not classed as an error (e.g.,  $A \rightarrow A \rightarrow A \rightarrow A \rightarrow A \rightarrow B$ ), unless the list order was violated (e.g.,

$A \rightarrow A \rightarrow A \rightarrow A \rightarrow A \rightarrow B \rightarrow A$ ), the chance of a correct response for items B, C, and D is 1 in 3 (33%). Thus, the chance of completing a trial correct was 0.9% ( $0.25 \times 0.33 \times 0.33 \times 0.33$ ). Reinforcement was only provided when all list items had been responded to in the correct order. Any violation of the order immediately terminated the trial and subjects entered a time-out period. A green boarding appearing around the stimulus reflects a correct response

to the identity of item  $n + 1$ , because the feedback following each response is identical. We note that the name “simultaneous-chaining paradigm” is an unfortunate choice of words for a paradigm that was developed, in part, to debunk chaining theory. Therefore, in the current paper, we will refer to the paradigm as the serial-order task.

The serial-order task is unique in the sense that it has been utilized with an extremely wide variety of species and adapted to assess multiple aspects of how serial-order behaviors are represented and executed. With respect to the diversity of species, the serial-order task has been utilized in work with adult humans (Colombo and Frost 2001), chimpanzees (Ohshiba 1997), a gorilla (Ross 2009), capuchin monkeys (D'Amato and Colombo 1988), crab-eating monkeys (Scarf and Colombo 2009), snow monkeys (Ohshiba 1997), rhesus

monkeys (Brannon and Terrace 1998; Terrace et al. 2003), marmosets (Koba et al. 2012), lemurs (Merritt et al. 2007, 2011), chickens (Scarf 2011), and pigeons (Scarf and Colombo 2010b, 2011; Straub and Terrace 1981; Terrace et al. 1977). This diversity provides a unique opportunity to compare the serial learning abilities of a range of species. In the current paper, we not only provided a comparative analysis of the measures that are traditionally derived from the serial-order task, we also compare species on some of the more recent adaptations of the original paradigm.

## Representation of a List

The most common performance measure derived from the serial-order task is the pairwise test. The

aim of the test is to determine what knowledge a subject acquires when learning a list. A list containing  $n$  items gives  $(n)(n-1)/2$  possible pairs. For example, on a 5-item list, ten pairs can be generated (AB, AC, AD, AE, BC, BD, BE, CD, CE, and DE). On the pairwise test, the subject is presented with each pair and must respond to the items in the pair true to the order in which they appeared in the original sequence. If presented with pair BD, for example, the subject must respond to the items in the order  $B \rightarrow D$  to obtain a reward. It is important to clarify that when we say that the subject is presented with pair BD we do not mean to imply that item B is presented on the left and item D on the right. In fact, the items of each test pair have an equal chance of being presented to the left or right of one another irrespective of their order in the original list. The performance of adult humans (Colombo and Frost 2001), monkeys (D'Amato and Colombo 1988), marmosets (Koba et al. 2012), lemurs (Merritt et al. 2007), and pigeons (Terrace 1987) on the pairwise test is shown in Fig. 2. Adults perform between 84% and 100% correct across the ten test pairs. Although the performance of monkeys and marmosets is not as good as that of adult humans, they generally perform above chance on all pairs. Similarly, the lemurs perform above chance on all pairs with the exceptions of pairs AB and CD. Finally, the performance of pigeons on the

pairwise test is as good as that of adult humans, monkeys, and marmosets, but only for test pairs that contain either item A or E. For these pairs (AB, AC, AD, AE, BE, CE, and DE), the pigeons performance ranged from 80% to 95% correct. In contrast, performance on test pairs that did not contain an end item (BC, BD, and CD) was no better than chance (50% correct). Thus, in the absence of item A or E, pigeons seem at a loss as to how to respond to the items of a pair.

With respect to the performance of adult humans (Colombo and Frost 2001), monkeys (D'Amato and Colombo 1988), marmosets (Koba et al. 2012), and lemurs (Merritt et al. 2007), the accuracy with which they respond suggests that over the course of learning the serial-order task they formed a representation of the list and use that representation to guide their behavior. By “guide their behavior” we simply mean that when a pair is displayed, the subject accesses their representation of item A and then searches for item A in the display. If they do not find item A displayed, they access their representation of item B and then search for item B in the display. If subjects are progressing in an orderly fashion through their representation and examining whether the current item in their representation is displayed, then we would expect the latency to respond to the first item of a pair to be a function of the position of that item in the list. In other

**Serial List Learning, Fig. 2** The performance of adult humans (Colombo and Frost 2001), monkeys (D'Amato and Colombo 1988), marmosets (Koba et al. 2012), lemurs (Merritt et al. 2007), and pigeons (Terrace 1987) on the

pairwise test. Data for marmosets are limited to pairs AB, AC, AD, BC, BD, and CD due to the fact they were trained on a 4-item, rather than a 5-item, list

words, they should take longer to respond to item D in pair DE than item C in pair CE, because in the case of pair DE the animal has to access three items in their representation (A, B, and C), whereas in the case of pair CE they only have to access two (A and B). A linear relationship between the latency to respond to the first item of a pair and the position of that item in the series is called the *first-item effect*. Figure 3 shows the latency to respond to the first item of a pair as a function of its position in the sequence for adult humans, monkeys, marmosets, lemurs, and pigeons. Adults, monkeys, marmosets, and lemurs all show a *first-item effect* in that the latency to respond to the first item of a pair increases as a function of the position of that item in the sequence. In contrast to these subjects, pigeons show no *first-item effect*.

If adults, monkeys, marmosets, and lemurs are solving the serial-order task by progressing through the sequence in an orderly fashion, as described above, a second prediction would be that the latency to respond to the second item of a pair should be a function of the number of items missing between the first and second item. For example, after responding to item C in pair CE, the subject would next access their representation and search for item D, and upon not finding it

displayed they would then access their representation and search for item E in the display and, upon seeing it, respond to it. In other words, the animal should take longer to respond to item E in pair CE than to item E in pair DE, because in the case of pair CE the subject has to access an additional item in their representation (D) before coming to item E, whereas in the case of pair DE there are no additional items to access. A linear relationship between the latency to respond to the second item of a pair as a function of the number of missing items is called the *missing-item effect*. Figure 3 shows the latency to respond to the second item of a pair as a function of whether the first and second items were separated by 0, 1, 2, or 3 missing items. Monkeys, marmosets, and lemurs show a *missing-item effect* (D'Amato and Colombo 1988; Koba et al. 2012; Merritt et al. 2007). Interestingly, adults do not show a *missing-item effect* when tested on the pairwise test (not shown in Fig. 3). Colombo and Frost (2001) suggested this may be due to the fact that adults realize that once a response is made to the first item of a pair, the second item can be responded to by default. Accordingly, when adults are tested with triplets that prevent them from being able to simply make a default response to the second item, they too show a *missing-item effect* (see Fig. 3).

**Serial List Learning, Fig. 3** Data for adult humans (Colombo and Frost 2001), monkeys (D'Amato and Colombo 1988), marmosets (Koba et al. 2012), lemurs (Merritt et al. 2007), and pigeons (Terrace 1987) derived from the pairwise test. The left panel depicts the *first-item*

*effect* and the right panel depicts the *missing-item effect*. Data for marmosets are limited to items A, B, and C for the *first-item effect* and 0 to 2 missing items for the *missing-item effect* due to the fact they were trained on a 4-item, rather than a 5-item, list

Overall then, adults, monkeys, marmosets, and lemurs perform at a high level on the pairwise test and display a *first-item effect* and a *missing-item effect*. These findings are consistent with the view that in the process of learning a 5-item serial-order task, subjects form an associative representation of the order  $A \rightarrow B \rightarrow C \rightarrow D \rightarrow E$ . It is important to note that this representation differs from an S-R chain in a couple of important ways. First, an associative representation provides a subject with an internal representation of the entire sequence of items, while an S-R chain does not. Second, even when only pairs of items are presented, an associative representation can be worked through successively in order to work out which item of a pair comes first. A chain of responses, however, makes it impossible for a subject to work out the order of pairs that do not contain item A, as the chain cannot be activated in the absence of this initial physical stimulus.

As noted above, in contrast to adults, monkeys, marmosets, and lemurs, pigeons perform poorly on the internal pairs of the pairwise test and show no *first-item effect* or *missing-item effect*. These findings have led several investigators to suggest that pigeons cannot form a representation on the serial-order task (D'Amato and Colombo 1988; Terrace 1993, 2006). How then, in the absence of forming a representation, do pigeons learn to respond to the items of a list in the correct order? One possibility is that, in contrast to adult humans and nonhuman primates, pigeons adopt an approach consistent with chaining theory. That is, the onset of the stimulus display (i.e., the five items appearing on the screen) may serve as a discriminative cue to respond to item A. In turn, responding to item A serves as a discriminative cue to respond to item B, and so on. In addition, pigeons learn to respond to item A first and avoid item E until last, allowing them to perform well on pairs that contain either item A or item E (Terrace 1993). Until relatively recently, this line of reason was used by several authors to conclude that pigeons acquire a qualitatively different representation than adult humans and nonhuman primates (D'Amato and Colombo 1988; Terrace 1993, 2006).

Rather than reflecting a qualitative difference, Scarf and Colombo (2010b) suggested pigeons'

failure on the internal pairs may be due to the sudden contextual change that a pigeon experiences when transferred from a 4- or 5-item list to the pairwise test. Indeed, when an internal pair (i.e., BC, BD, and CD) is presented, the context for responding to each item has changed. Take the case of pair BD. Responding to item B is no longer preceded by a response to item A, and responding to item D is no longer preceded by a response to item C. The result of this sudden contextual change is that pigeons perform poorly on the internal pairs.

To test the possibility that the poor performance of the pigeons on the internal pairs was the result of this contextual change, Scarf and Colombo (2010b) trained two groups of pigeons on a 5-item list and, after reaching criterion, simply trained them on just the BD pair. To control for learning effects, half of the birds were trained on the BD+ pair (in which reinforcement was provided when the items were responded to in the order true to that of the original sequence), and the other half were trained on the BD- pair (in which subjects were reinforced for responding to the items in the order opposite to that learned in the original sequence). If subjects have no knowledge of the order of the items in an internal pair, then subjects learning the positive pair and the negative pair should acquire them in a comparable amount of time. Consistent with the view that pigeons form a representation of the sequence, rather than rely on a simple response chain, subjects trained on the BD+ pair achieved the 90% criterion in significantly fewer trials than did subjects trained on the BD- pair (Fig. 4).

## Knowledge of Ordinal Position

Of course, a representation of a list can come in many forms. One possibility is that adult humans (Colombo and Frost 2001), monkeys (D'Amato and Colombo 1988; Harris et al. 2007), marmosets (Koba et al. 2012), lemurs (Merritt et al. 2007), and pigeons (Terrace 1987) acquire simple item-item associations on the serial-order task. Alternatively, they may acquire knowledge of each item's ordinal position (e.g., associating

**Serial List Learning, Fig. 4** The performance of pigeons on the BD+ and BD- pairs (Scarf and Colombo 2010b)

item A with the 1st position, item B with the 2nd second position). In the early work on serial learning in humans, derived lists were a popular method to distinguish between these possibilities. For example, Ebenholtz (1963) trained two groups of subjects on a 10-item list composed of nonsense syllables. Once the subjects acquired the list, one group was trained on a derived list in which the even or odd items from the first list maintained their ordinal position, and the other group was trained on a derived list in which the ordinal position of the even or odd items from the first list were changed. Ebenholtz (1963) found that the group trained on the maintained list learned their list faster than participants learning the changed list, suggesting that subjects encoded the ordinal positions of the list items and used that information to guide responding on the derived lists.

Relative to the large number of species that have been tested on the pairwise test, only monkeys and pigeons have been trained on derived lists (Chen et al. 1997; Scarf and Colombo 2011). In the first of these studies, Chen et al. (1997) trained two monkeys on four 4-item lists (List 1: A1 → B1 → C1 → D1, List 2: A2 → B2 → C2 → D2, List 3: A3 → B3 → C3 → D3, and List 4: A4 → B4 → C4 → D4). Following training, subjects learnt four derived lists. In two of the derived lists, items maintained their ordinal position (Maintained 1: A2 → B4 → C1 → D3; Maintained 2: A3 → B1 → C4 → D2), while in the other two the ordinal position of the items was

changed (Changed 1: B3 → A1 → D4 → C2; Changed 2: D1 → C3 → B2 → A4). Both subjects acquired the two maintained lists much faster than the two changed lists, indicating that both relied on their knowledge of ordinal position to guide responding on the derived lists (Fig. 5).

Following Chen et al. (1997), Scarf and Colombo (2011) trained three pigeons on three 4-item lists (List 1: A1 → B1 → C1 → D1, List 2: A2 → B2 → C2 → D2, and List 3: A3 → B3 → C3 → D3) and then presented them with maintained and changed lists. In contrast to Chen et al. (1997), only the ordinal position of the interior items was maintained (e.g., A1 → B2 → C3 → D1) or changed (e.g., A1 → C2 → B3 → D1). Scarf and Colombo (2011) argued that derived lists constructed in this manner provide a more precise test of subjects coding of ordinal position because the first and last items can be discriminated on the basis of factors other than their ordinal position. The data for two of Scarf and Colombo's (2011) pigeons are shown in Fig. 5. Both subjects got significantly more trials correct on the maintained lists than the changed lists, suggesting pigeons, similar to monkeys, used their knowledge of ordinal position to guide responding.

## Planning List Responses

Recently, variations of the serial-order task have been used to investigate the planning abilities of chimpanzees (Biro and Matsuzawa 1999),

**Serial List Learning, Fig. 5** The performance of monkeys (left panel) (Chen et al. 1997) and pigeons (right panel) (Sarf and Colombo 2011) on maintained (M1 and M2) and changed (C1 and C2) derived lists. It is important to highlight the fact the monkey data report trials to

criterion, with higher values reflecting a slower rate of learning. In contrast, the pigeon data report percentage correct over the first six sessions of training; thus, lower values reflect a slower learning rate

monkeys (Beran et al. 2004; Sarf et al. 2011a), marmosets (Koba et al. 2012), and pigeons (Sarf and Colombo 2010a). With respect to the representation of sequences, the ability to plan is of interest because it provides an additional way of distinguishing between animals that rely on a chain of responses and those that form a representation. Indeed, Lashley (1951) suggested spoonerism demonstrate that sequences are planned in advance and that they would not occur if a chain of responses was the mechanism underlying language. Further, Miller, Galanter, and Pribram (1960) noted in their influential book, *Plans and the Structure of Behavior*, “Therein resides the crucial difference between a chain of actions and a Plan of action. When a chain is initiated with no internal representation of the complete course of action, the later parts of the chain are not intended. When a Plan is initiated, the intent to execute the later parts of it is clear.” (pp. 62). It follows that an animal that relied on a chain of responses would display no evidence of planning at all.

In the first study to investigate planning using the simultaneous chaining paradigm, the chimpanzee Ai was trained to respond to three Arabic numerals, drawn from the range 0 to 9, in ascending order (Biro and Matsuzawa 1999). In addition to these baseline trials, “switch” probe trials were introduced. On switch trials, after Ai responded to

the first item, the on-screen positions of the second and third items were exchanged. When switch trials were responded to correctly, Ai’s response latencies to the second item were longer than on baseline trials (Fig. 6). Biro and Matsuzawa (1999) suggested that the increased response time on switch trials reflected Ai’s updating of the motor response plan formed at the outset of the trial. Similar findings have now been observed with monkeys (Sarf et al. 2011a), marmosets (Koba et al. 2012), and pigeons (Sarf and Colombo 2010a) (Fig. 6).

## Numerical Lists

Thus far, we have only considered lists in which the order of items is arbitrarily defined by the experimenter. For a wide range of behaviors, however, the relation between items or behaviors is defined by a rule. Two prototypical human examples are language and numerical concepts. With respect to language, in the comparative literature, there are a growing number of studies investigating animal grammatical abilities (ten Cate 2017). With respect to numerical concepts, modifications of the serial-order task have been used to assess whether monkeys (Brannon and Terrace 1998), lemurs (Merritt

**Serial List Learning, Fig. 6** The response latency of chimpanzees (Biro and Matsuzawa 1999), monkeys (Scarf et al. 2011a), marmosets (Koba et al. 2012), and pigeons (Scarf and Colombo 2010a) on normal and switch trials

**Serial List Learning, Fig. 7** Performance over the stimulus sets used during training for monkeys (left panel) (Brannon and Terrace 1998), lemurs (middle panel) (Merritt et al. 2011), and pigeons (right panel) (Scarf et al. 2011b). The dashed line represents chance. The

chance line differs for each species due to the fact monkeys were trained on 4-item lists (Chance = 0.9%), lemurs were trained on pairs of items (Chance = 50%), and pigeons were trained on 3-item lists (Chance = 8.33%)

et al. 2011), and pigeons (Scarf et al. 2011b) can form abstract numerical rules. For example, Brannon and Terrace (1998) trained two monkeys on 35 4-item numerical lists, with each list item containing 1, 2, 3, or 4 elements. Consistent with the view that monkeys were deriving a numerical rule (i.e.,  $1 \rightarrow 2 \rightarrow 3 \rightarrow 4$ ), over the course of learning the 35 lists, the monkeys performance on the first session of training steadily increased (Fig. 7). To determine whether the numerical rule was specific to the training numerosities (e.g., nominal categories) or more abstract, subjects were tested on pairs of numerosities drawn from the range of 1 to 9. The pairs were one of three types: familiar-

familiar (F-F) pairs contained two numerosities drawn from the training range (e.g., 1 vs. 2, 1 vs. 3, etc.), familiar-novel (F-N) pairs contained one trained numerosity (i.e., 1, 2, or 3), one novel numerosity drawn from the values 4 to 9 (e.g., 1 vs. 4, 2 vs. 9), and novel-novel (N-N) pairs contained two novel numerosities drawn from the values 4 to 9 (e.g., 5 vs. 6, 7 vs. 9). Not only did the monkeys perform above chance on F-F and F-N pairs, they also performed above chance on N-N pairs. Given N-N pairs contained numerosities the monkeys had not seen before, their performance on N-N pairs suggests they developed an abstract numerical rule that was not tied to the training numerosities.

More recently, both lemurs (Merritt et al. 2011) and pigeons (Scarf et al. 2011b) have been trained using comparable procedures to those employed by Brannon and Terrace (1998) with monkeys. Rather than training subjects on 4-item lists, the lemurs were trained on pairs of items drawn from the range 1 to 4 (e.g.,  $1 \rightarrow 2$ ,  $3 \rightarrow 4$ ,  $1 \rightarrow 3$ ), while the pigeons were trained on 3-item lists (i.e.,  $1 \rightarrow 2 \rightarrow 3$ ). In contrast to monkeys, the lemurs failed to show any clear improvement in performance over the stimulus sets during training, while pigeons displayed increasing performance over the 35 3-item lists during training (Fig. 7). Even in the case of pigeons, however, their performance on the training lists was markedly below the proficiency displayed by Brannon and Terrace's (1998) monkeys. Despite differences in performance during training, the lemurs and pigeons performed above chance on the F-F, F-N, and N-N pairs (Merritt et al. 2011; Scarf et al. 2011b). In addition, several other aspects of the lemurs' and pigeons' performance suggest they extracted a similar to numerical rule to Brannon and Terrace's (1998) monkeys. For example, their discrimination performance was dependent on the ratio of the paired items. In other words, both 1 versus 3 and 6 versus 8 are separated by one item, but the 1 versus 3 discrimination (ratio = 0.33) is easier to discriminate than the 6 versus 8 discrimination (ratio = 0.75), and this was true for both monkeys and pigeons.

## Conclusion

Sequences lie at the heart of everything humans do. From reciting the alphabet to writing a novel, from playing chopsticks on a piano to performing Beethoven's 5th Symphony, from planning what is for dinner to planning one's career path, behaviors must be performed in a specific sequence in order for success. The serial-order task has proven a versatile tool with which to explore the foundations of sequence learning across a variety of different species, from how serial-order information is represented to planning. Although it was initially thought some of these abilities were unique to certain orders (e.g., primates but not

pigeons), it is now clear that the ability to process serial-order information is conserved across a wide range of species. This view is bolstered by findings employing other serial-order paradigms. For example, Fagot and Cook (2006) demonstrated that both monkeys and pigeons display one of the hallmarks of serial memory, the serial position curve.

With the advent of recent computational models of serial-order learning (Enquist et al. 2016) and work on the neural representation of sequences (Dehaene et al. 2015), we are moving ever closer to solving Lashley's (1951) problem of serial-order behavior and providing a window into some of the most complex aspects of human thought (e.g., language). Much like the behavioral data we have reviewed, however, solving the problem will require us to take a comparative neuroscience approach, moving beyond a sole focus on primate models, and providing an answer that has the power to explain serial-order behavior across a diverse range of species and behaviors.

## Definition

Serotonin is a molecule with no informative value on its own. It acquires biological properties through the organization of the neurons producing and releasing it, and through its numerous receptors. A system of neurotransmission like serotonin can modulate the activity of nervous tissues in animals, and ultimately impact cognition and behavior.

## Introduction

Serotonin (5-hydroxytryptamin, 5-HT) is a small molecule playing the role of neuromodulator in virtually all complex organisms of the animal kingdom but its overall function is still not well understood. As quoted by Azmitia and Jacobs in 1992, “although 5-HT has been implicated in a vast array of physiological and behavioral processes in vertebrates, it appears to be essential for none of them” (Jacobs and Azmitia 1992, p. 165). This would be a perfect definition of a neuromodulatory role upon central nervous

system (CNS) functions, reaching its quintessence in case of 5-HT systems over other neuromodulatory systems like catecholamines, acetylcholine, histamine, or neuropeptides.

It has been reported for several years that the 5-HT systems can modify cognition and behavior, and this property has been shown at many occasions in invertebrates as well. Often considered as a neurotransmitter positively involved in well-being, in part due to the positive effects of selective 5-HT reuptake inhibitors (SSRI) in some patients suffering from mood disorders, the situation is much more complex as 5-HT participates in stress responses and mood disorders, irrespective of its levels. In several cognitive tasks and behavioral responses, 5-HT can mediate opposite outcomes. This is related to (1) the diversity of its receptors having different affinities for 5-HT and intracellular signaling pathways and localization, and (2) the widespread presence of 5-HT in the CNS capable of acting on several neurobiological targets at the same time. Thus, 5-HT is intimately linked to fine-tuning adaptive behaviors, perhaps by delaying responses for appropriate behaviors and by inhibiting learned responses that are not currently adaptive (Bari and Robbins 2013; Soubrié 1986).

In this chapter, the organization of the 5-HT systems in numerous vertebrates and invertebrate species is briefly mentioned. Thereafter, the influence of 5-HT in cognition and some behaviors has been illustrated with the motor activity and arousal, feeding behavior, circadian rhythm, sleep, social status and aggressiveness, anxiety, mood, learning and memory, and cognitive flexibility.

## Organization of 5-HT Systems in Animals

The organization of the 5-HT systems is completely different between species ranging from a limited number of cells in *Aplysia*, *Drosophila* (100 immunoreactive cells) to several thousand neurons in vertebrates localized in the midbrain raphe nuclei. The variety and the heterogeneity of 5-HT neurons have been highlighted in vertebrates and invertebrates. In general, the 5-HT

systems in animals comprise 5-HT neurons which share a particular shape made of thousands of varicosities, leading to the concept of volume transmission (De-Miguel and Trueta 2005), and several 5-HT receptors (5-HTRs). The specificity of 5-HT transmission comes also from reuptake sites, which are specific (serotonin transporter, SERT) and less specific including catecholaminergic transporters. The distribution of these transporters around the synapses permits the regulation of the extracellular concentrations of 5-HT extrasynaptically. Thus various modalities of neurotransmission have been reported in the case of 5-HT including classical synapses, neurohumoral, and/or paracrine influences (De-Miguel and Trueta 2005). The latter has been well shown in insects (female cricket *Acheta domestica*) where 5-HT innervates the genital chamber muscles without identified synapses. These modalities are more or less present across the animal kingdom.

5-HT acts on a variety of receptors. In mammals, 5-HTRs are organized in seven families (5-HT<sub>1-7</sub>R) and more than 16 subtypes have been described. They have been characterized for several years regarding cloning, pharmacology, and brain expression (Saudou and Hen 1994). Conversely, 5-HTRs in some invertebrates are less known (Saudou and Hen 1994) despite the prediction that it could be almost similar. Briefly, four 5-HT receptors named 5-HT<sub>1Adro</sub> (or d5-HT<sub>1A</sub>), 5-HT<sub>1Bdro</sub>, 5-HT<sub>2dro</sub>, and 5-HT<sub>7dro</sub> have been discovered in drosophila, and two in crustaceans (5-HT<sub>1ACrust</sub> and 5-HT<sub>2BCrust</sub>). In molluscs, two 5-HT receptors were cloned belonging to 5-HT<sub>1</sub> and 5-HT<sub>2</sub> families in *Lymnaea stagnalis* whereas five were cloned in Aplysia. In a pond snail (*Helisoma trivolvis*) two receptors types (5-HT<sub>1Hel</sub> and 5-HT<sub>7Hel</sub>) have been cloned and characterized.

## Motor Activity and Locomotion

5-HT directly acts on all motor centers and even in muscles. Indeed, 5-HT has been reported to act directly in neuromuscular junction in insects, crustacean, annelids, or gastropods (see review

Wu and Cooper 2012). In crustacean or gastropods' neuromuscular junction, 5-HT enhances synaptic transmission by a presynaptic action. Such an action has been well described in Aplysia where the contraction of the buccal muscle is facilitated by 5-HT. In leech neuromuscular junction, Retzius cells innervate muscles and release 5-HT leading to a reduction of muscle contraction.

5-HT can also increase the motor activity by acting on motoneurons or central pattern generators (CPGs) in insects, crustaceans, annelids, and vertebrates. In mammals, it is well known that the application of 5-HT on isolated preparations of spinal cord from a newborn rat initiates a fictive locomotion corresponding to alternating patterns of neuronal activity normally controlled right and left paws. In insects, 5-HT enhances the motoneuron drive in drosophila larvae and in leeches, 5-HT depletion or 5-HTR blockade impaired swimming activity. It is noteworthy that several mechanisms triggered by 5-HT are often combined and these mechanisms refer to specific actions of 5-HT at the level of the motoneurons. For instance, in Crustacean motoneurons, 5-HT increases tonic discharge at 10  $\mu$ M and decreases it at 100  $\mu$ M. These two responses involve different types of receptors: the excitatory effect involves 5-HTR localized in the neurites that acts by closing a K<sup>+</sup> conductance; the inhibitory response involves 5-HTR receptors located on the axon close to the action potential initiation segment acting by opening a K<sup>+</sup> conductance.

Acute activation of 5-HT neurons disrupts normal locomotion activity in adult flies (Majeed et al. 2016). 5-HT being apparently absent in the fly's neuromuscular junction (Wu and Cooper 2012), such an effect could correspond to an important regulatory role of motor programs by 5-HT systems. This has been further evaluated by using mutations in the 5-HT biosynthetic enzymes and by knock-down 5-HTRs expressed in mushroom bodies (d5-HT<sub>1AR</sub>, d5-HT<sub>1BR</sub>, d5-HT<sub>2R</sub>, and d5-HT<sub>7R</sub>) using RNAi strategy. Animals expressing an RNAi for d5-HT<sub>1BR</sub>, d5-HT<sub>2R</sub>, and d5-HT<sub>7R</sub>, but not d5-HT<sub>1AR</sub> in mushroom bodies show increased motor behavior. Thus, d5-HTRs expressed in mushroom bodies differentially modulate motor programs in fly larvae.

## Arousal

The link between arousal/activity and 5-HT system has been proposed for several years (Jacobs and Azmitia 1992; Soubrié 1986). This idea comes in part from studies performed in mammals including cats, rodents, or humans. During the rapid eye movement (REM) phase of sleep, 5-HT neurons stop firing coinciding with the atonia of skeletal muscle groups during REM. Conversely, oral activity, grooming, biting, or chewing are associated with a marked activation of a group of 5-HT neurons. These neurons are also activated by stimuli applied to the head and the face. It has been suggested that 5-HT neurons, like CPGs, are activated by repetitive motor activities (Jacobs and Fornal 1999). While stressful situations are not necessarily associated with a change of firing rate of 5-HT neurons, acidosis can increase the activity of a subset of 5-HT neurons (chemosensitive) in various raphe nuclei.

The roles of 5-HT in arousal have been studied in gastropods and notably in *Aplysia*. Two major classes of arousal elements exist: localized versus general (Jing et al. 2009). Actions of localized arousal elements are often limited to one class of behavior. They may mediate specific effects of arousal. General arousal elements may influence multiple classes of behaviors, and mediate both specific and nonspecific effects of arousal. 5-HT can act as either localized or general arousal elements. Prominent roles of 5-HT systems in arousal are conserved in gastropod molluscs. The role of 5-HT in arousal is unclear in *Drosophila* where dopamine could promote arousal (Nall and Sehgal 2014).

## Sleep and Circadian Rhythm

As already mentioned, 5-HT has a role in sleep in mammals. The activity of 5-HT neurons is lower during slow wave sleep and almost null during REM. It probably contributes to the circadian rhythm because a substantial projection of the 5-HT neurons of the raphe nuclei has been identified in the suprachiasmatic nucleus, a hypothalamic nucleus involved in the regulation of the

wake-sleep cycle (Monti 2011). 5-HT is involved in the synchronization of the circadian clock located in the suprachiasmatic nucleus in pigeons, and a positive correlation between the circadian rhythms of activity and serum 5-HT levels has been reported in ringdove. In addition, 5-HT is the metabolic precursor of melatonin, known for its regulatory role on the circadian system.

Multiple 5-HT receptors participate in the regulation of sleep in mice. 5-HT<sub>1A</sub>R and 5-HT<sub>1B</sub>R reduce REM sleep whereas 5-HT<sub>2A</sub>R, 5-HT<sub>2C</sub>R, or 5-HT<sub>7</sub>R do the opposite. The mechanisms contributing to these effects are different for all the receptors (Monti 2011).

5-HT could play an inhibitory role on the effects of light on circadian rhythmicity as proposed in vertebrates (Jacobs and Fornal 1999). Interestingly, entrainment of the *Drosophila* circadian clock to light involves the light-induced degradation of the clock protein *timeless*. This mechanism is inhibited by 5-HT via d5-HT<sub>1B</sub>R. Additionally, d5-HT<sub>2</sub>R in the third instar larvae would play a role in the circadian activity by controlling the anticipatory behavior. Sleep was demonstrated to be different from circadian rhythm. Elevating 5-HT promotes sleep in *Drosophila* likely via d5-HT<sub>1A</sub>R. For instance, RNAi knockdown of tryptophan hydroxylase caused a loss of night-time sleep (Artiushin and Sehgal 2017). *Drosophila* with suppressed d5-HT<sub>1A</sub>R exhibit reduced and fragmented sleep, whereas d5-HT<sub>1A</sub>R expression in mushroom bodies rescues the normal phenotype (Nall and Sehgal 2014).

In Crustaceans, the situation is much less known compared to *Drosophila*. Regulation of circadian rhythm is mainly operated via the Eye-stalk X-organ-sinus gland system where 5-HT and melatonin have been largely found.

## Feeding

The involvement of 5-HT in feeding behavior is an important topic in 5-HT research (Voigt and Fink 2015). In humans 5-HT-based pharmacological agents have been used as anti-obesity agents such as D-fenfluramine. The anorectic effect of

D-fenfluramine has been associated with its property to enhance 5-HT release in laboratory animals, indirectly leading to the stimulation of 5-HT<sub>2C</sub> receptors. Due to noxious cardiac effects, D-fenfluramine has been withdrawn while the 5-HT<sub>2C</sub> agonist lorcaserin has reached the market. The influences of 5-HT in feeding behavior are probably numerous as several receptors have been implicated (5-HT<sub>1A</sub>R, 5-HT<sub>1B</sub>R, 5-HT<sub>2C</sub>R) and brain regions including subregions of the hypothalamus. 5-HT, through its different receptors, would prolong the satiety signals and limit the size of the meal.

Parallels have been done with the situation in invertebrates and notably, in *C. elegans* feeding (Luedtke et al. 2010). 5HT via the 5-HTR SER-7 activates the pumping behavior required to take bacteria from the environment into the gut. 5-HT is also required for food-dependent induction of bursts as well as for maintaining their high rate of pumping through two distinct mechanisms, one via SER-1 for food-induced pumping, the other triggered by exogenous 5HT via SER-7.

5-HT also participates in insect feeding behavior. In *Rhodnius prolixus* after blood meal, the Malpighian tubules increase their secretion 1000-fold to preserve salt and water balance. This activity is controlled by neuropeptides and 5-HT. In drosophila, the alteration of the 5-HT system by feeding larvae with 5-HT, 5-HT precursor or inhibitor of tryptophan hydroxylase impaired locomotion and feeding in the larvae (Majeed et al. 2016). Blocking or enhancing 5-HT transmission in larvae or adult also resulted in impairment of locomotion and feeding behavior.

## Social Status and/or Aggressiveness

A number of studies in invertebrates and vertebrates have reported that 5-HT participates in social interactions including sexual behavior or the social status (Edwards and Spitzer 2006; Jacobs and Azmitia 1992). The social status is usually addressed through fights leading the animals to establish the status of dominant (winner) and subordinate (loser) (Edwards and Spitzer

2006; Miczek et al. 2002; Stevenson and Rillich 2012). Pairing two crayfish for 15 days leads to fights. During this period, the sensitivity to 5-HT application of giant fibers encompassing escape behavior circuit evolves. Whereas in isolate and dominant crayfish, 5-HT enhances the response to mechanosensory inputs, 5-HT has little or no effect in the subordinate. The change of sensitivity to 5-HT is progressive during the 15 days and is associated with modifications of body posture and the neurobiological network underlying escape behavior (Edwards and Spitzer 2006). In addition, the 5-HT system could have an acute role on the issue of the fight. Injection of 5-HT can considerably increase the aggressiveness of the crayfish having a slightly lower physical size (usually detrimental for the issue of the fight). Yet, it is difficult to argue for a permissive role of 5-HT on aggressiveness. Indeed, the 5-HT precursor attenuated aggression in pigeons without affecting feeding in dominant members, and decreased the time spent running away by subordinates. It is noteworthy that in the reptile *Anolis carolinensis*, the chronic exposure to the SSRI sertraline, likely via an enhancement extracellular 5-HT levels, reverses the social dominant status.

The studies performed in insects give similar uncertainty as regards the serene side of 5-HT. 5-HT would depress escape responses in aggressive crickets and oppose the action of octopamine which is required for aggressive responses (Stevenson and Rillich 2012). Nonetheless, 5-HT depletion leads to hyperactivity without affecting the level of aggressiveness. After a fight, losers exhibit escape behavior and have lower 5-HT levels. The findings are similar in the fruit flies drosophila. On one hand, the increase or decrease in 5-HT synthesis does not alter aggression in drosophila. On the other hand, increase in 5-HT synthesis or activity of 5-HT neurons elicits aggression whereas the disruption of 5-HT transmission led to reduced fighting ability. The 5-HT aggressive drive in drosophila would be due to a single 5-HT neuron expressing a d5-HT<sub>1A</sub>R (Alekseyenko et al. 2014).

The connection between 5-HT and social status and aggression has been the object of several studies in mammals and notably mice (Miczek

et al. 2002). This is a complex field of research as there are many ways and parameters to experimentally address aggressive behaviors and social interaction that are dependent on the strain as well. Lower tissue levels of 5-HT coincide with higher level of aggressiveness, but, again, it is not always the case. In macaques, the antisocial behavior marked by violence and aggression is associated with low levels of the metabolite of 5-HT in the CSF. It has been reported in mice or healthy volunteers that a diet without tryptophan, an essential amino acid only found in diet and necessary for the production of 5-HT, increases the level of aggressiveness under specific circumstances.

Different 5-HTRs have been shown to be involved in aggressive responses. Mice lacking 5-HT<sub>1B</sub>R exhibit higher rates of aggressive episodes, whereas 5-HT<sub>1A/1B</sub>R agonists such as eltopazine reduce several aspects of aggressiveness in mice and/or rats (de Boer and Koolhaas 2005; Miczek et al. 2002). The efficacy of these compounds is unclear as it could be related to the reduction of 5-HT neuron activity inherent to the stimulation of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> autoreceptors and/or the direct stimulation of these receptors on neurobiological networks. In drosophila, the 5-HT<sub>1A</sub>R agonist 8-OHDPAT increases the level of aggression, mainly wing threats and fencing components, whereas the 5-HT<sub>2R</sub> agonist DOI decreases overall aggression, mainly lunging and boxing components (Johnson et al. 2009).

Beyond the intrinsic complexity of aggressive behaviors, the definite proof that the above-mentioned mechanisms engaged by the 5-HT system are specific of aggressive behavior is uncertain. While an indirect action of 5-HT on motor activity can be tested, an action of 5-HT on other behaviors indirectly modulating the decision to fight or to flee with an opponent cannot always be discarded. For instance, the apparent anti-aggressive effect of eltopazine in mice could be implemented by its anxiogenic effect.

## Anxiety

Anxiety is indeed a complex dimension with several forms in animal behavior (Millan 2003). Anxiety

has been recently acknowledged in invertebrates (Fossat et al. 2014) and it has been the object of numerous clinical and preclinical studies in mammals. Anxiety is considered a secondary emotion because it occurs when the stressor is absent or not clearly identified.

In drosophila, anxiety-like behavior resulting from stress is sensitive to the benzodiazepine and anxiolytic drug diazepam and share similarities with rodent anxiety-like behavior (Mohammad et al. 2016). The anxiety-like behavior is altered when acting on d5-HT<sub>1B</sub>R, d5-HT<sub>2B</sub>R, and SERT but not 5-HT<sub>1A</sub>R and d5-HT<sub>2A</sub>R. Specifically, knockdown and overexpression of d5-HT<sub>1B</sub>R and dSERT increased and decreased anxiety-like parameters, respectively; knockdown or impairment of d5-HT<sub>2B</sub>R reduced anxiety-like behavior (Mohammad et al. 2016). Using an aquatic dark/light plus-shaped maze, it has been shown in crayfish that repetitive electric shocks produced behaviors compatible with anxiety (Fossat et al. 2014). The anxiety-like behavior, associated with an increase in tissue 5-HT in brains, can be triggered by the administration of exogenous 5-HT, reduced by a cocktail of 5-HTR antagonists and by the potent anxiolytic chlordiazepoxide.

In rodents, extensive researches indicate that several 5-HTR can be targeted with agonists or antagonists depending on the subtype considered to modulate anxiety-like behaviors. It has to be kept in mind that the multiple circuits involved in different forms of anxiety complicate the choice of one specific target (Millan 2003). The 5-HT agents being used in clinic have widespread effects on 5-HT neuron activity and are either SSRI or partial 5-HT<sub>1A</sub>R agonist.

## Mood

A crayfish regularly defeated by a stronger congener during fights and then harassed by the winner presents an increase of anxiety-like behavior directly related to the harassment period duration (Bacque-Cazenave et al. 2017). If this social stress is prolonged for 2 weeks, the loser will progressively present a subordinate behavior, while the winner will become the dominant. This change in

social status is accompanied by a loss of 5-HT modulatory effects not only on the giant fiber escape circuit but also on the locomotor network. In both cases, a depression of neural activity is observed. Although it is difficult to evoke a depression-like behavior for the subordinate crayfish, the loss of 5-HT modulation resulting from chronic stress was recently demonstrated in another invertebrate, the drosophila, and clearly associated with a depression-like state. In drosophila, a depression-like state can be induced by vibration stress over 3 days (Ries et al. 2017). This state, which is controlled by 5-HT signaling in alpha and gamma lobes of the mushroom bodies, is ameliorated by lithium chloride. The behavioral changes correlate with reduced 5-HT release at the mushroom body. These changes can be relieved by feeding the metabolic precursor 5-hydroxytryptophan or sucrose, which results in elevated 5-HT levels in the brain acting at d5-HT<sub>1A</sub>R.

These recent findings in drosophila remind the reported role of 5-HT in depression symptoms observed in mammals and humans, in particular. Modification of 5-HT levels in CSF or the brain has been occasionally found in case of major depression associated with suicidal tendencies. Moreover, it has been reported that a diet without tryptophan could promote depression in individuals vulnerable to mood disorders. However, a strict relationship between depressive symptoms and 5-HT content does not exist in mammals. The 5-HT systems seem to play an important role in the mechanism of action of antidepressant drugs whatever their pharmacological action in interaction with the other monoaminergic systems (Hamon and Blier 2013).

## Learning and Memory

5-HT system has been known to be involved for a long time in learning and memory. It was originally described in an elementary behavioral response in Aplysia at the level of neuromuscular synapses in buccal motoneurons. The persistent facilitation of the withdrawal reflex is related in part to 5-HT producing an increase in release of

glutamate at sensory-motor neuron synapses. This involves a 5-HTR coupled to adenylate cyclase (Lee et al. 2009). Other data in invertebrates have also reported short- and long-term plasticities notably in drosophila and honeybee *Apis mellifera* (Blenau and Thamm 2011). The long-lasting plasticity occurs in vertebrates with some analogy with what has been described in invertebrates. The 5-HT system appears to play a role in behaviors that involve a high cognitive demand and in memory improvement. Multiple 5-HTR subtypes are involved, sometimes in opposite manner, often in different manner, in memory processes (Meneses 2015).

## Impulsive/Compulsive Dimension and Behavioral Flexibility

Impulsive and compulsive behaviors have been reported in invertebrates including Aplysia, honeybee, and drosophila, but the role of 5-HT in these nonadapted responses has never been studied in those species as far as we know. In humans, maladaptive decision-making is a common core symptom of diseases like obsessional compulsive disorders, Tourette's syndrome, attention deficit disorder, pathological gambling, or addiction. Numerous laboratory tests have been created in order to address these dimensions and it has been shown that 5-HT plays an important role.

The impulsive/compulsive trait involves complex interactions between prefrontal and orbital cortices, the basal ganglia, a group of subcortical structures involved in the control of motor behavior, and monoaminergic systems of the midbrain including 5-HT neurons (Dalley et al. 2011). Reduction of 5-HT has been proposed to result in premature responses in numerous behavioral tests. Behavioral (cognitive) flexibility means that the animal can modify its behavior in response to modifications of the environment. 5-HT depletion in rodents and primates causes perseverative errors in behavioral tasks such as extinction and reversal learning paradigms. This suggests that the animals without 5-HT have difficulties in stopping responses to previously

rewarded stimuli which are no longer reinforced. The actions of 5-HT involve at least 5-HT<sub>2A</sub>R and 5-HT<sub>2C</sub>R.

## Conclusion

This chapter briefly reports the widespread influence of 5-HT in adaptive behaviors and cognition in both vertebrates and invertebrates. It is a modulatory system capable of mediating opposite effects on cognition and behaviors. It is thus challenging to attribute a specific role to 5-HT in animals except a neuromodulatory role. The neuromodulatory influence of the 5-HT system is evolutionarily well conserved.

## Service Dogs

Naomi D. Harvey

School of Veterinary Medicine and Science,  
The University of Nottingham, Sutton Bonington,  
UK

## Synonyms

Assistance dogs; Working dogs

## Definition

A dog that has received specific training to perform specialized tasks that aid people with disabilities, including visual impairment, reduced mobility, and psychiatric and neurological disorders.

## What is a Service Dog?

All service dogs are united by the fact that they have undergone a specialized training regimen, which has provided them with a behavioral repertoire not normally found in other dog populations that enables them to assist (or serve) people with physical or mental disabilities. Service dogs come in many different and varied forms. Some are well known and long established, such as guide dogs, which aid people with visual impairments, while others such as seizure alert dogs are relatively new. Another type of dog often confused with service dogs is the therapy or support dog. Support or therapy dogs are used to provide companionship and sometimes to help with treatment of psychiatric disorders such as depression or post-traumatic stress disorder. However, therapy and support dogs do not undergo specialist training and do not perform tasks to assist people, so under US and UK law, they are not considered to be service dogs (Bennett and Desai 2016; Brennan 2014).

## Types of Service Dog

Service dogs are differentiated by the tasks they are trained to perform and the people whom they serve. The tasks that a service dog can be trained to perform are varied and can be quite complex.

Guide dogs for the blind undergo perhaps the most complex training regimen of all service dogs, as they are specifically responsible for their owner's safety in all environments outside of the home. These dogs are trained very carefully to be able to walk to a straight line until instructed to turn left or right, ignore distractions, identify and indicate obstacles in the owners path (including those that would not be an obstacle to a dog, such as a pen on the floor or branches hanging at human head height), find safe alternative routes around obstacles, sit at curbs until instructed to move forward, and, perhaps most advanced of all, disobey a command to walk forward if they determine that there is an oncoming danger such as a car coming toward them (Audrestch et al. 2015). Contrary to many lay views of guide dogs, however, the dog does not choose the route nor make the decisions but instead works in partnership with their visually impaired owner through a series of interactions characterized by complementary cooperation (Naderi et al. 2001).

Hearing dogs are trained to signal their owners when a sound occurs, such as the ring of the doorbell, but they are also trained to retrieve their owner when another person in the household calls them. In this capacity, hearing dogs act as valuable safety aids as well as aids to communication between people.

Seizure response dogs assist people with disorders such as epilepsy. These dogs can be trained to retrieve help when their owner has a seizure or to stand guard over them as they do. Some, such as seizure alert dogs, are specifically trained to warn their owners of an imminent seizure before it begins, enabling the person to get to a safe place in advance (Dalziel et al. 2003).

Disability assistance dogs are specifically trained to help with everyday tasks that can be impeded for a person with mobility issues. The training each dog receives is often specifically tailored to the needs of the individual client and

can include tasks such as picking up and retrieving objects, opening and closing doors, pressing buttons, loading and unloading washing machines, and assisting with dressing/undressing (Lane et al. 1998).

Autism assistance dogs (also known as sensory signal dogs or social signal dogs) are trained to interrupt repetitive movements made by those with autism. When working with children with autism, they can also serve a role in road safety, as they are trained to sit at a curb and not move forward until instructed to; if the child pulls away toward the road before it is meant to, the dog sits and prevents them from moving via an attached dog-child harness (Anon 2016).

## Why Dogs?

People often ask whether any animal could be trained as a service animal and what makes the dog so suited to the task. Other types of animals have been trained to perform tasks for people with disabilities such as monkeys and miniature horses; however the dog is by far the main species utilized. Not only are dogs more practical than other animals, as they take less time to train and can accompany their owners wherever they go, but dogs have a unique set of cognitive abilities that make them exceptionally well suited to working as a service animal. Dogs have been domesticated for longer than any other species (at least 15,000 years (Frantz et al. 2016)) and have been artificially selected over thousands of years to work cooperatively with humans in various working roles from hunting to guarding (Clutton-Brock 1995). Further, dogs can be habituated during the sensitive period of development (at 3–12 weeks of age) to the anthropogenic environment, which may prove stressful for other species that lack this habituation window.

Domestication of the dog involved processes that increased their sociality, communication ability, and co-cooperativeness, and while we cannot say dogs have the same cognitive capacity as humans, it has been suggested that these behavioral facets are functionally analogous to those of the Human Behavior Complex which involves sociality, behavioral synchronization, and constructive skills (Topál et al. 2009). Topál and

colleagues suggest that there is a suite of functional behavior they referred to as the Dog Behavior Complex that they argue contributed to the success of dogs in the human environment. The first of these skills is *sociality*, which is evidenced by a predisposition to form close bonds with humans (Gácsi et al. 2005) and the predisposition of dogs to be attracted toward humans, which wolves are lacking (Frank and Frank 1982). Additionally, dogs have been shown to exhibit various types of *behavioral synchronization*, which promotes interspecies relationships, including rule following (Kubinyi et al. 2003), social learning (Range et al. 2007), emotional synchronization (Vas et al. 2005), and complementary cooperation (Naderi et al. 2001). The role of a guide dog, in particular, has a strong requirement for the dogs to be able to synchronize their behavior to that of their human companion.

Another aspect of the Dog Behavior Complex is the dog's ability not only to learn and follow rules but also to anticipate the behavior of another individual (Kubinyi et al. 2003), which aids synchronized behavioral interactions (Topál et al. 2009). While dogs do not have human linguistic skills, they have demonstrated the ability to be able to *constructively communicate* with humans, initiating communication via direct gaze, gaze alternation, vocalization, and physical contact, traits which are more prevalent in dogs than wolves (Miklósi et al. 2003). The predisposition of dogs to gaze at the human face may have also led to the ability of dogs to, at least partially, read human facial expressions to enable better perception of our emotions (Racca et al. 2012). Dogs have also been shown to be able to adapt their behavior in order to "request" help by providing information to people whose knowledge is lacking, to help the dog achieve a goal (Virányi et al. 2006). Such skills allow for interspecific information sharing and complex cooperation, which are necessary prerequisites for forming successful human-animal working relationships. Indeed, the dog's ability to read human behavioral cues and alert humans to an oncoming event is precisely what enables seizure alert dogs to perform their duties, a role which was originally

untrained and performed innately by a small number of pet dogs (Dalziel et al. 2003).

### Selecting Suitable Dogs

When considering which dogs are suitable to be a service dog, the most important factor is individual differences in behavior (referred to from hereon as personality). Animal personalities develop based upon interactions between an animal's genetics and its social and nonsocial environment (Saetre et al. 2006). Studies reporting heritability of personality traits in dogs suggest that 0–46% of behavioral variation is heritable, with differences between traits (Goddard and Beilharz 1983; Saetre et al. 2006; Wiener et al. 2015). Thus, experiential or epigenetic processes mediate a large proportion of behavioral variation between individuals. Recent evidence from a study of juvenile guide dogs suggests that the dog's social environment and how it interacts with its social partners may be most salient in shaping its adult personality (Harvey et al. 2016).

Traditionally, service dogs tend to be medium-sized breeds such as Labradors, golden retrievers, German shepherd dogs, and their crosses, with hearing dogs tending to be smaller sized such as spaniels. However, not every dog of these breeds will be suitable as a service animal due to considerable within-breed differences in personality, and many other breeds of suitable size to perform the required tasks have been successfully trained. Evidence from guide dog breeding programs demonstrate that dogs bred by guiding organizations are more successful as guide dogs than those of the same breeds sourced from other breeders (Pfaffenberger et al. 1976). While some of this difference may undoubtedly be caused by breeding selection toward dogs with more suitable traits, a large part is also due to the organizations having control over the early-life experiences of the puppies and the ability to begin socialization habituation early on (Pfaffenberger et al. 1976).

Service dog organizations need to routinely evaluate the behavior of the dogs they train in order to decide upon the most suitable training regimen for each dog and to determine their suitability to the training program. The vast majority of published studies on service dog behavior

assessments have been conducted with the aim of selecting guide dogs, with at least one study investigating the potential of utilizing shelter dogs as a source of dogs for training as assistance dogs such as hearing dogs or dogs that aid people with mobility issues (Lucidi et al. 2005). While there may be overlap in the basic traits required to be a successful service dog, for example, to be highly trainable, eager to work with humans as a cooperative unit and not be fearful, aggressive, or defensive, different organizations often have slightly differing requirements depending on the exact circumstances the dog is expected to work under and tasks they are expected to perform. Hearing and disability assistance dogs, for example, tend to need high energy levels and enthusiasm to work at any time, whereas guide dogs need to be able to be calm and steady in a variety of circumstances and are often expected to sit or lie quietly under desks and tables or on buses for extended periods of time. Successful guide dogs are typically low on fearfulness, not easily distracted/impulsive, nonaggressive, and highly trainable and adaptable (Duffy and Serpell 2012; Goddard and Beilharz 1983; Harvey et al. 2017).

### Evidence for Cognitive Differences in Service Dogs

While service dogs undergo a strong selection pressure so that only those with suitable traits should undergo training, there is evidence that the level of training itself and the experience of being a service dog impact upon the dog's cognitive capabilities. Dogs that have been intensively trained using positive reinforcement methods have been found to exhibit a more proactive response in problem-solving tests, improving their problem-solving capabilities (Marshall-Pescini et al. 2008), and are more reliant upon their own judgments when humans provide them with misleading information in food choice tasks than untrained dogs (Prato-Previde et al. 2008). However, a recent study on adolescent guide dogs found that juveniles (as yet untrained for service work) that performed better in certain problem-solving tasks were more likely to be selected for work as a guide dog later in life (Bray et al. 2017), so the exact cause and effect of the relationship between a dog being highly trained and exhibiting

improved problem-solving ability has yet to be established.

Gaunet 2008 sought to investigate whether guide dogs differed from pet dogs in their ability to constructively communicate with their owners in an unsolvable task paradigm, specifically whether they adapted their behavior to the visual status of their owners. Gaunet concluded that while the guide dogs exhibited incidental learning, adding an additional method of communicating with their visually impaired owners to their repertoire via sonorous mouth licking in the presence of food, there were no differences between guide dogs and pet dogs in the use of other methods of communication such as gaze alternation between the food and the owner, vocalization, and contact with the owner.

While aspects of cognition have undoubtedly impacted upon the success of dogs in service roles, the role played by individual differences in cognition toward service dog suitability has yet to be fully evaluated.

## Sex Determination

Sex differences refer to the numerous qualities and characteristics that vary between the sexes. There are different sexes in most animals, as well as some insects, and even plants. In humans, an individual's sex is determined by their chromosomes. Humans are born with 46 chromosomes in 26 pairs. On the 23rd pair, the chromosomes are known as either X or Y chromosomes. If someone is born with two X chromosomes, they are female. If there is one X and one Y in the pair, then they are male. These are the most common outcomes; however, in rare cases, there can be other variants. One in every thousand humans will be born with only one sex chromosome, and at a similar rate, some individuals are born with three sex chromosomes (Aydin et al. 2019). Additionally, some people are born with some cells containing an XY pair, while other cells contain XX; this is known as intersex. Hormonal variation during fetus gestation can also contribute to sex determination. When a Y chromosome is present, around the tenth week of pregnancy, a gene called *SRY* acts upon the embryonic gonads to cause differentiation into male testes (Becker et al. 2005). In an absence of the Y chromosome, the embryonic gonads will become ovaries. Embryonic testes secrete hormones that act on cells in the body and brain to make them male-typical (Nef and Parada 2000). Testosterone is one of these hormones, and in the presence of testosterone, neuronal connections in the brain will begin to form that are more commonly found in males than females and that are responsible for certain behavioral and functional traits (Becker et al. 2005). Read Arnold (2016) for more information.

## Hormones

One key difference between male and female humans is the level of hormones throughout an individual's life cycle. Three main hormones are present in both sexes – estrogen, progesterone, and testosterone – but to different extents. On average, higher levels of testosterone are commonly found in males as compared to females,

higher levels of estrogen are commonly found in females as compared to males, and equal levels of progesterone are found in both males and females. An exception to this would be during the luteal phase of the female menstrual cycle, during which progesterone levels are elevated (Oettel and Mukhopadhyay 2004).

Estrogen is synthesized in all vertebrates, as well as some insects, and has a variety of functions in both male and female humans. In females it helps with memory, cholesterol regulation, heart and muscle health, maturation and maintenance of bone density, blood clotting, and regulation of sugar and insulin sensitivity and increases fat storage (Barakat et al. 2016). In addition, in the female reproductive system, estrogen helps stimulate the growth of the egg follicle and enhances and maintains the membrane that lines the uterus (Hampson 2019). In males, it is primarily responsible for bone density maintenance and liver function, helping to metabolize fats and sugars (Wibowo and Wassersug 1999). In the male reproductive system, estrogen aids in the maintenance of libido, erectile function, and the creation of sperm (Schulster et al. 2016).

Progesterone is a hormone that is only present in birds and mammals, but aids in several important functions within these animals. In humans of both sexes, progesterone has been proven to improve sleep and stimulate weight gain and appetite, as well as playing a role in the immune system, cardiovascular system, respiratory system, and kidney function (Oettel and Mukhopadhyay 2004). In males, progesterone is responsible for creating testosterone and aiding in the creation of sperm. In females, progesterone helps thicken the lining of the uterus to prepare for a fertilized egg (Patel et al. 2015). In humans, testosterone is responsible for several important processes, including encouraging bone growth and density, stimulating the production of red blood cells, promoting muscle development, and improving mood and libido (Rothman and Wierman 2009; Smith et al. 2013). In males, specifically, testosterone aids in erectile function and prostate growth and function (Smith et al. 2013).

Males and females both go through regular cycles of hormonal change. Male testosterone levels

fluctuate throughout the day, whereby they are highest in the morning and lowest at night (Brambilla et al. 2009). In contrast, female estrogen and progesterone fluctuate monthly. The female hormone cycle is part of the menstrual cycle, which is composed of three parts: the follicular phase, the ovulatory phase, and the luteal phase. The follicular phase begins on the first day of menstrual bleeding, prior to the release of the egg, and lasts about 14 days. In this phase levels of estrogen (20–50 pg/mL; (Hampson 2019) and testosterone (200–300 pg/mL; Abraham 1975) start out at their lowest and gradually rise, until they reach their highest peak of the cycle (130–200 pg/mL is typical for estrogen, 500 pg/mL for testosterone). Production of progesterone by the ovaries is negligible during this time. Behaviorally, females display high energy, high positive affect, and low anxiety. Working memory tends to be improved during this time, as estrogen enhances working memory. The ovulatory phase, which lasts approximately 16–32 h, occurs when the egg is released into the uterus. During this phase estrogen increases, causing the luteinizing hormone to peak. The Luteinizing hormone is responsible for ultimately triggering the release of the egg. Libido tends to be highest during this phase. The luteal phase is the period of time after the egg has been released, which lasts about 14 days, unless fertilization occurs. Progesterone is at its highest concentration at 100–200 pg/mL, estrogen plateaus at 100–150 pg/mL, and testosterone falls to 300 pg/mL (Hampson, 2019). Cortisol levels also rise during this time due to higher progesterone levels, and as a result, females tend to experience low energy, increased negative affect, and heightened reactivity to stress. If fertilization does not occur, then this phase will end in a sudden drop in estrogen and progesterone. This results in the shedding of the uterine lining, causing menstrual bleeding and the beginning of the next cycle.

Levels of hormones also fluctuate dramatically depending upon the stage of life. For females, hormone levels rise as puberty is reached, but by 18 the hormonal levels are still only ~50% of levels reached at full reproductive maturity. The highest levels of hormones can be measured during ages 25–35, before they begin to slowly

decrease (Hampson, 2019). Once menopause is reached, around age 50, hormone levels decrease more dramatically. As males reach puberty, testosterone levels increase. They continue to increase until they peak in their 20s. After approximately age 30, testosterone begins to slowly decline by about 2% per year (Smith et al. 2013). Some men will experience a significant decrease in testosterone after the age of 60.

## Aggression

Though males tend to be seen as the more aggressive sex, both males and females usually display an equal amount of aggression, with females in some species displaying more aggression than males (Choleris et al. 2017). The difference largely comes in the types of aggression displayed. Males tend to express physical and direct aggression, whereas female aggression is usually indirect. This can be seen in mice, with males exhibiting territorial aggression through attacking, biting, and lock fighting, in contrast to females who aggress through pushing and chasing (Choleris et al. 2017). This can also be seen in humans, as males are more likely to assert dominance with direct physical confrontation, while females are more likely to manipulate social relationships (group exclusion, rumors, etc.) as a form of indirect aggression.

Testosterone is often characterized as a hormone that causes aggression. This is often true in many species; however in humans there seems to be a more complex relationship between aggression and testosterone. Testosterone in humans seems to induce social status supporting behaviors, through both prosocial and antisocial behaviors. For those who are higher in status, testosterone increases displays of more dominant aggression. Conversely, an increase in testosterone in those with a lower social status is associated with a reduction in aggression to those above them in the social hierarchy and an increase of aggression to those below them (Rejeski et al. 1988). One study found that females who received testosterone before playing a bargaining game actually increased the amount of money offered to their partner, when compared to those given a

placebo (Eisenegger et al. 2010), which displays prosocial behavior in an act to maintain their social status and avoid negative social consequences.

## Cognition

Hormonal influence on embryonic neural networks causes some cognitive differences to be seen between the sexes. For example, testosterone has an organizational effect on the orbitofrontal cortex (OFC), which is responsible for decision-making. Potentially as a result, males tend to be better at tasks that engage the OFC (Evans and Hampson 2015). A meta-analysis of regions of activation in response to emotion-eliciting tasks showed differences in areas of activation between the sexes. For males compared to females, these areas include the medial prefrontal cortex, anterior cingulate cortex, frontal pole, and mediodorsal nucleus of the thalamus. Females show distinct activation in the bilateral amygdala, hippocampus, and regions of the dorsal midbrain including the periaqueductal gray/superior colliculus and locus coeruleus (Filkowski et al. 2017). This supports research that has found that the difference in working memory lies not in performance quality but instead in differing networks utilized. Females tend to activate more limbic (e.g., amygdala and hippocampus) and prefrontal structures (e.g., right inferior frontal gyrus), whereas males tend to activate a broader network that includes more parietal regions (Hill et al. 2014).

On average, males have been shown to have improved ability on spatial tasks compared to females, and females have been shown to have improved abilities on verbal and perceptual speed tasks compared to males (Hyde et al. 2016). These different proclivities have been postulated to be the reason behind further differences, such as an enhanced visual episodic memory performance in males and enhanced auditory episodic memory in females (Pauls et al. 2013). One theory that may explain the spatial differences from an evolutionary perspective posits that species which require males to travel greater distances to gain access to mates leads to a spatial advantage over females

who did not face the same pressure (Gaulin et al. 1990). This was shown in a study which compared a monogamous strain of voles to a strain that did not pair bond. It found that males in the nonmonogamous strain covered significantly more distance than females and that the sexes in the monogamous strain were equally well-traveled. Better spatial ability was indeed found in the males compared to females in the non-monogamous strain, whereas the difference did not exist in the pair bonding strain (Galea et al. 1996; Gaulin et al. 1990).

Sex differences are also frequently found in social learning, which is the process of acquiring new knowledge through observing and mimicking others. In humans as well as rodents and birds, females tend to show superior social learning when compared to males (Brodin and Utku Urhan 2014; Wang et al. 2014). Estrogen may play a role in this, as mice, rats, and gerbils have been found to have increased social learning during times of estrogen flux (e.g., pregnancy, parturition; Choleris et al. 2017).

A distinct difference in cognition between the sexes also arises in self-assessment. When asked to assess their intellectual abilities, males consistently overestimate their abilities, whereas females significantly underestimate their abilities. This is termed the male hubris, female humility effect, or simply the hubris-humility effect (HHE; Storek and Furnham 2012). This can have societal implications, as well as affect results in research, and thus should be noted in any study assessing cognitive differences between the sexes.

## Mating and Attraction

In general, the sex that must invest the most into offspring tends to be the most selective in choosing a mate. For mammals, this is most often the female. Males, consequently, must invest significant energy into being the best candidate for females to choose from. As a result, mating displays can be seen from males across many species, and intra-sex competition is highest in males. Some ways in which males have evolved to increase their chances of mating are often through

being brightly colored or displaying loud calls, in an effort to show that they can still evade predators effectively even when blatantly visible and heard. One interesting reversal in these roles is in the poison arrow frog. Males of this species care for and raise offspring from the time of fertilization of the eggs and thus invest significantly more time and energy into offspring than females do. In this case, it is the males who are the choosiest, and the females must compete with each other to win the favor of male poison arrow frogs (Wells 1978).

Hormones continue to play a role in sex differences when it comes to attracting and choosing a mate. The menstruation cycle dictates what kind of mate females prefer at certain times, in addition to their attractiveness to males. During the short window of time during which females are ovulating, their preference switches from mates that would be beneficial as long-term partners to those who would have the greatest genetic advantage. While ovulating, females tend to be more attracted to mates that have symmetrical faces and masculine features, as this signals a potential mate's heritable fitness. At other times in the cycle, different male characteristics are valued more highly, such as conscientiousness, loyalty, and good parenting qualities. This switch is most readily seen in females who are assessing short-term mates and is less apparent in those who are searching for long-term partners. In a similar fashion, females tend to be rated as more attractive by males while they are ovulating as opposed to other times during their cycle.

Menstruation dictates mating in many mammals outside of humans as well. In rodents, females will only pursue a mate when estrogen and progesterone are both at peak levels (Choleris et al. 2017).

## Health

Some significant differences between the sexes that are often overlooked are the differences in mental and physical health. In humans, females are much more vulnerable to developing Alzheimer's disease, depression, and anxiety and suffering strokes. Males have a greater risk of

developing Parkinson's disease and are more likely to be afflicted with schizophrenia than females, as well as experience earlier onset and display more severe cognitive symptoms (Choleris et al. 2017). Additionally, disorders of social behavior such as autism spectrum disorders and violence and impulsive aggression have a higher incidence rate in males compared to females (Choleris et al. 2017).

Many of these issues can be attributed to the differences between the structural organization of neural networks, or to the different evolutionary challenges faced by each sex. For example, females' higher rates of diseases associated with activation of the stress response system may be due to the evolutionary benefit of being more risk averse than males. With a greater investment in offspring comes a greater loss in losing them; thus, threats are a greater risk to females compared to males. As such, females experience enhanced defensive behaviors and stress responses, which prepare them to be more responsive to potential threats. This may be what makes them more vulnerable to a disorder of this system, causing increased instances of anxieties, phobias, depression, and post-traumatic stress disorders (Choleris et al. 2017). Similarly, males have been more involved in territorial defense and must engage in more intra-sex competition for resources and access to mates. This engagement in aggressive activities may be one cause of the higher rates of social behavior disorders in males.

Other biological differences between the sexes may further exacerbate differences in health. The sex differences in hormone levels have led to distinctions in disease presentation. Estrogen provides a protective role in the immune system, whereas testosterone has toxic effects, and this can partially account for the higher incidence rates of Parkinson's disease in males compared to females (Invernizzi et al. 2009). Differences in mitochondria lead to a difference in incidence rates for multiple diseases and may be one of the causes of higher incidence rates of Alzheimer's disease in females. A key factor in the development of Alzheimer's is mitochondrial dysfunction. In healthy individuals, female mitochondria produce only half the amount of hydrogen peroxide that the mitochondria of males do (Silaidos

et al. 2018). This difference may therefore have significant consequences for female vulnerability to the development of Alzheimer's disease. For a variety of reasons, males tend to be more vulnerable to infections than females. The immune response is different between males and females, with females demonstrating a stronger cellular and humoral immune response (Invernizzi et al. 2009). This may be due to estrogen having an enhancing effect on the immune system, or the X chromosome carrying more genes that relate to the immune system. Whatever the case, a side effect appears to be a significant increase in autoimmune diseases. Of those who suffer from autoimmune diseases, 80% are female.

There is a significant sex difference in the treatment of diseases as well, correlating to the overall mortality rates of these diseases. Females are more likely to have a stroke, with symptoms that often differ significantly from males. The outcomes of females suffering a stroke tend to be much worse than for males, with females facing longer hospitalization times, double the likelihood of being transferred to long-term care, and a higher chance of mortality (Choleris et al. 2017). Similarly, heart disease is the leading cause of death in females; however, cases of heart disease are often not recognized by medical professionals due to atypical presentation and deviation from "classic" male symptoms. As such, mortality and morbidity rates in female patients are frequently higher when compared to males (Campo 2016).

## Definition

In sexually reproducing species, sex ratio is the proportion of males to females in a given population. It is usually expressed as the number of males per 100 females.

## Introduction

Depending on the context, sex ratio might be measured in a particular life stage, e.g., ratio at the time of fertilization (also called primary sex ratio), ratio at birth (secondary sex ratio), ratio in organisms that have reached sexual maturity or adulthood (tertiary sex ratio), ratio of sexually active and fertile organisms (operational sex ratio), or ratio in organisms past reproductive stage (quaternary sex ratio). The ratio tends to be approximately 1:1, which is explained by Fisher's principle (see below). However, a significant deviation from that rule is observed in many species, either permanently or periodically. In humans, sex ratio at birth is sometimes skewed because of factors such as infanticide, sex-selective abortions, age of mother at birth, or environmental factors (Davis et al. 1998).

In 1982, Eric L. Charnov, an American evolutionary ecologist, published a book on the prediction of sex ratios based on a species' natural history. He attempted to identify the equilibrium when allocating resources to female versus male function in simultaneous hermaphrodites, equilibrium of time of sex change and sex order in sequential hermaphrodites, and equilibrium in the ratio maintained by natural selection in dioecious species (having both male and female reproductive organs). He also analyzed when natural selection favors an individual's ability to adjust its allocation to female versus male function, as a reaction to particular life history or environmental variables. He analyzed the conditions favoring evolutionary stability for various states of dioecy or hermaphroditism and when mixtures of various sexual types are stable (Charnov 1982).

## Fisher's Principle

Fisher's principle is an evolutionary model outlined by Sir Ronald Fisher, British geneticist and statistician, in his book *The Genetical Theory of Natural Selection*, published in 1930. It explains why the sex ratio in sexually reproducing species is close to the so-called "Fisherian" ratio of 1:1, which is considered

evolutionarily stable (Fisher 1930). Fisher argued that the process of natural selection leads to sex ratio adjustment. If the total parental investment (such as resources, energy, or time) in the offspring of both sexes is equal, then the birth ratio of sexes should be 1:1.

An important addition to Fisher's theoretical discussion of sex ratio was provided by Trivers and Willard (1973) that stated that, in mammals, females are able to adjust sex ratio of their offspring in response to the maternal condition. Despite the fact that Fisher's principle secures the 1:1 sex ratio, evolution will favor deviations from this rule if one sex has a probability of achieving greater reproductive payoff than the other. The findings of Trivers and Willard suggest that the reason for promoting such disproportion is that, in good condition, mothers should invest more in producing males, because sons of a high quality are expected to out-reproduce daughters of high quality. Consequently, mothers who are in poor condition should invest more in producing females, because daughters of low-quality are expected to out-reproduce sons of low quality. The implication is that parental ability to adjust offspring sex ratio depending on the quality of conditions should be favored by natural selection. Data on sex ratio of mammals supports this hypothesis: as maternal condition increases, females tend to produce more males than females.

## Sex Ratio in Nonhumans

Most animals maintain a relatively stable operational sex ratio, but some are known for having their sex determined not just by genes but also by, e.g., environmental factors or hormonal changes (e.g., Ferguson and Joanen 1982; Pike and Petrie 2005). Proper assessment of a sex ratio is neither easy nor straightforward. It has been observed that deviation from the 1:1 ratio is widespread in marine crustacea; there are male-female relationships of discrete patterns, so instead of overall sex ratio, calculation of different within-size-class ratios should be taken into consideration (Wenner 1972).

Temperature-dependent species have a higher within-species variance in sex ratios than

chromosome-determined species (Bókonyi et al. 2019). For example, in American alligators, sex of the individual is dependent on incubation temperature of the egg. Females are hatched from eggs incubated at a lower temperature than males, who require higher temperatures (Ferguson and Joanen 1982). Temperature-based sex determination is also found in turtles. However, a study performed on eggs incubated in the same temperature shows evidence that some heritable differences in sex determination exist as well (Bull et al. 1982). Temperature can also influence sex in fish, such as in Nile tilapia (Abucay et al. 1999), and the effect for interaction of genotype and temperature is observed in species such as the Atlantic silverside (Conover and Kynard 1981).

Environmental determination of sex ratio is also observed in the potato root eelworm, a parasite. In eelworms, the ratio can differ depending on primary and lateral roots, and on the intensity of their parasitic infection (Ellenby 1954). Environmental influence on primary sex is also observed in dioecious plants. Maternal parents in close proximity to males produce female-biased progeny sex ratios (Stehlik et al. 2008). In copepods, sex ratio differs between families depending on whether females produce eggs continuously after just one mating, or they require several matings (Kiørboe 2006). In fig wasps, females adjust offspring's sex ratio in response to the level of inbreeding and the intensity of mate competition in the local population (Herre 1985). Parasitic wasp females adjust offspring sex ratio depending on whether they are the first or second wasp parasitizing the host. The first one biases strongly towards daughters, and the second one varies sex ratio depending on local mate competition level (Werren 1980). In collared flycatchers, females manipulate offspring sex ratio depending on the male partner's genetic quality (Ellegren et al. 1996). To summarize, not all species of flora and fauna follow the strict Fisherian ratio rule; in some species, sex is moderated by various environmental factors. In short, the sex ratio tends to be that which is most likely to propagate copies of the parents' genes in that environment.

In mammals, one way of increasing eventual offspring production is to vary the sex ratio of offspring as a function of the benefits and costs of producing daughters versus sons. There are at least three factors that may affect sex ratio in mammalian offspring: cooperation or competition between siblings or between parents and siblings; differences in the relative fitness of female and male offspring; and sex differences in viability during early growth or in energy requirement. There is growing evidence that in many species there remains significant variation in mammalian birth sex ratio, which suggests continued adaptive manipulation of sex ratio. However, there are also other mechanisms affecting sex ratio at birth, and they are not likely to reflect adaptive manipulation, because the distribution of observed trends in sex ratio does not conform to the assumptions of any adaptive theory in a significant way. Some studies, however, argue that such trends might be adaptive within a particular population if the sex ratio differs with the benefits or costs of producing female and male offspring, such as a hypothetical population finding a very good and stable source of food, and therefore being able to afford the more costly sex of offspring (Clutton-Brock and Iason 1986).

Potentially adaptive significance of sex ratio variation caused by parental and environmental conditions is reported not only in mammals but also in birds. Findings suggest that sex ratio at birth could have been interfered with by steroid hormones and gonadotropins; however, whether it is an adaptive sex ratio adjustment or merely a consequence of physiological constrain is a subject of debate (Krackow 1995; Navara 2018).

There are, however, exceptions to the expectations of the Trivers-Willard theory. For example, in American kestrels, the sex ratio of offspring is correlated with female body size. Parents can adjust the sex of their offspring depending on the amount of resources available and as the food supply declines, the proportion of males hatching increases. Also, parents in poorer health produce more male-biased offspring and smaller females produce more males (Wiebe and Bortolotti 1992). In Seychelles warblers, biased sex production, not embryo mortality, is the cause of a bias in hatching

sex ratios. Pairs on bad-quality territories produced 77% sons, and pairs on good-quality territories produced 13% sons. Pairs that transferred from a poor to a high quality territory subsequently produced significantly more females (Komdeur et al. 1997). These exceptions may be caused by, for example, reversed sex characteristics in the species, such as females being physically larger in order to compete for mates.

## Sex Ratio in Humans

In humans, sex ratio at birth is approximately 1:1, and research measuring sex ratio has been conducted all around the globe, producing over 100 years of data. Sex ratio varies across age groups and geographical locations, and several factors can influence sex ratio, including race, birth order, plural birth, duration of gestation, and parental age, psychological stress, and health history. The sex ratio produced in relation to these factors, however, is not consistent over time for a given country, or across countries at a given time. It has been observed that in the USA, between 1950 and 1972, fetal and neonatal death more frequently occurs in females, which biases the birth sex ratio slightly towards males (McMillen 1979); however, proper estimation of this bias is difficult and affected by factors such as sex-selective abortions. In infancy, boys have higher mortality rates because they are more susceptible to disease (Pongou 2013). For the USA, sex ratio at birth for Hispanic and African-American ethnic groups is lower than for white ethnic groups. Also, in a white ethnic group, sex ratio at birth was 1.04 if the gestational age was 33–36 weeks, but if the age was shorter (<28–32 weeks) or longer (37 weeks or more), the sex ratio was 1.15 (Branum et al. 2009). Women tend to live several years longer than men, which biases sex ratio in older generations towards women.

In 1990, economist Amartya Sen analyzed whether birth sex ratios are affected by sex-selection, e.g., aborting female fetuses, or natural causes, such as greater vulnerability of male fetuses. Sen argued that strong socioeconomic factors, e.g., one-child policy in China or India's

dowry system, affect prenatal sex-selection. Some disagree with this argument; however, for example, Garenne (2004), who observed that, in many African nations, e.g., Nombia, Botswana, and Angola, there are fewer boys born than girls, which is not the case for other nations.

Sex ratio imbalance differs across the globe as a consequence of various factors, such as environmental stressors in the form of, e.g., cold weather; women exposed to colder temperatures tend to spontaneously abort (i.e., miscarry) male fetuses more frequently, and therefore, more females are born. It has also been shown that males living in colder temperatures tend to live longer, thus raising sex ratio in later life stages (Catalano et al. 2008). Helle et al. (2009) found the reverse effect; they documented that environmental stress, such as war or warmer temperatures, skew human birth sex ratio towards more frequent male births in Northern Europe. In females, experiencing stress during pregnancy, such as malnutrition, increases fetal deaths among males, in particular, leading to a female-biased sex ratio (Catalano et al. 2008). Due to the contradictory results regarding stress experienced by mothers during pregnancy on survivability of fetuses, more studies are needed to fully understand the effect. It has been found that some types of environmental pollution leading to exposure to persistent organochlorine pollutants, which are endocrine disruptors, increases the amount of ejaculated spermatozoa carrying the Y-chromosome, which might alter the sex ratio of offspring (Tiido et al. 2005). A longitudinal study on a Finnish population reported changes in sex ratio caused by environmental chemicals and showed that the birth sex ratio of males to females has decreased. It was found that the peak of male birth dominance occurred before the introduction of hormonal drugs and pesticides and the period of industrialization; after that, the sex ratio decreased. The researchers excluded the possibility that the change occurred because of other factors, such as birth order, age difference of parents, or parental age (Vartiainen et al. 1999). Finally, there has been identified an effect of father's age on sex ratio of offspring. Younger fathers had significantly more sons than older fathers. Mother's age did not affect a child's sex

(Jacobsen et al. 1999). To sum up, sex ratio in humans is a subject to various pressures, and the final sex ratio observable in a given population is a resultant of all of them.

## Introduction

In sexually reproducing animals, males usually search and compete for mates more actively than females do, whereas females are choosier than males when selecting mates (conventional sex roles). Accordingly, in sexually dimorphic animals, males often develop elaborate weapons or ornaments (Trivers 1972). Female-only care of offspring is much more ubiquitous than male-only care in many animal taxa. Moreover, in species with biparental care, females generally invest more in caring for their offspring. As the parental investment to offspring is a trade-off with the investment to mate acquisition, the evolution of these two life history traits are intimately linked (Fromhage and Jennions 2016). Therefore, sex differences in brooding behaviors are often treated as sex roles. Sex role reversal denotes reversion in one or more of these gender roles in reproduction, that is, masculine females or feminine males.

## Evolution of Conventional Sex Roles

The reasons for the evolution of conventional sex roles are still being debated. By definition, males

produce smaller gametes (spermatozoa), which are usually produced in much higher numbers than the ova in a population (anisogamy). Therefore, a male who secures multiple mating opportunities can pass many more gene copies to the next generation than a female can. Historically, this difference in the potential reproductive rate, or the resultant male bias in a pool of sexually mature adults at a given point in time (operational sex ratio), has been considered as the major determinant of conventional sex roles (Trivers 1972).

However, the sum of male reproductive success is equal to that of females in a population (Fisher's condition), and the “mean” reproductive success should be equal between the sexes in a population with an adult sex ratio of 0.5. Hence, anisogamy itself cannot explain the evolutionary maintenance of conventional sex roles.

Recent theoretical and comparative studies (Kokko and Johnstone 2002; Fromhage and Jennions 2016; Fromhage et al. 2016; Janicke et al. 2016) demonstrate that the following factors, which are associated with anisogamy (but not anisogamy itself), are important for determining sex roles: (1) sexual selection is usually stronger in males (not all, but some males can produce many more offspring than most females, resulting in a larger variance in reproductive success); (2) females usually have a “time-lag” between insemination and fertilization of eggs (in animals with internal fertilization) during which they are no longer available for mating in a population of adults; (3) females can mate with several males, resulting in uncertainty of paternity compared with maternity. Consequently, males usually invest more energy in mate acquisition and less in brooding than females do.

## Evolution of Reversed Sex Roles and Examples

Reversed sex roles are considered to evolve when one or more of the aforementioned conditions are violated. Fishes of the infraorder Teleostei are well known for their sex role reversal in parental care (Janicke et al. 2016). In contrast to many other animal groups, male-only care is more common than female-only or biparental care in teleost

fishes. In some species, females use sex-specific ornaments to attract males (potential care givers) and engage in female-female competition for territories (including potential nest sites for males). Because eggs are fertilized externally, male fish experience lower uncertainty of paternity. Additionally, the primary tasks associated with male parental care are supplying oxygen (fanning) and defending against predators, both of which enable males to simultaneously care for multiple clutches from multiple females. Therefore, parental investments by male fish are less likely to be paid at a cost to mate searching. Moreover, in some species, eggs cared for by males attract additional mates, resulting in the reinforcement of parental investment by sexual selection (Ah-King et al. 2005).

Similar phenomena are reported for some insects. In the assassin bug *Rhinocoris tristis* (Insecta: Hemiptera: Reduviidae), males can simultaneously care for eggs from up to seven different females. Interestingly, although male-only care is the norm of the species, females care for their own eggs when males are not available (reviewed in Shuker and Simmons 2014).

Male waterbugs of the family Belostomatidae (Insecta: Hemiptera) also care for eggs. Females lay dozens of eggs on a substrate (such as a plant stem) or on the back of the male mate, during which time the pair will repeatedly copulate. This behavior is considered to be a male adaptation to avoid taking care of unrelated eggs. Females actively search and compete for male caregivers. Moreover, since males do not mate during paternal care periods, females sometimes destroy an egg batch already cared for by a male to take over the mate. For this group of insects, in which males can care for only one egg batch from a single female at a time, it is presently unclear why males, not females, are the sole caregivers (Shuker and Simmons 2014).

Female-only or biparental care of broods is the norm for birds (Cockburn 2006). However, male-only care is reported for some unique species that represent only 1% of class Aves. Male-only care predominates in ratites (Infraclass Palaeognathae: ostriches, kiwi, emu, etc.). As in fishes, ratite males can care for eggs from multiple females

simultaneously. Additionally, the young are relatively mature and mobile upon hatching (i.e., precocial) and do not require biparental provisioning efforts.

The suborder Charadrii (waders) is another bird taxon with many representatives exhibiting male-only care. For example, female spotted sandpipers (*Actitis macularius*) compete for territories, in which several males provide care for her clutches. Like waterbugs, male sandpipers cannot care for multiple clutches at a time, so there is continuing debate on why males are the predominant caregivers. One possible explanation is that the cost of care is higher for females than males. In this group of birds, paternal care is relatively common in species that migrate to high latitudes, where it seems to be difficult for females to produce more than one clutch if they engage in brooding.

As illustrated in the aforementioned examples, the evolution of parental care is intimately related to the evolution of other sex roles, i.e., mate attraction, mate searching, intrasexual competition, and mate choice. These numerous aspects of sex roles are considered to coevolve under a complex set of natural and sexual selective pressures (Fromhage and Jennions 2016).

Strongly female-biased adult sex ratio can also make males (and their sperm) a limited resource for female reproductive success, and thus can result in sex role reversals, as paternal care of offspring does. In the butterfly species *Acraea encedon* (Insecta: Lepidoptera: Nymphalidae), females form aggregates (leks), presumably, to attract males in populations where male-killing bacteria (*Wolbachia*) persists, making males rare. Only males of this species engage in lekking behavior in populations that have nearly equal sex ratios (reviewed in Shuker and Simmons 2014).

Nutritional contributions from males to females also may cause reversed sex roles (reviewed in Yoshizawa et al. 2014). Males of dance flies (Insecta: Diptera: Empididae) donate prey items to females as nuptial gifts. Because larger gifts prolong copulation, nuptial gifts are considered to be a sexually selected male trait for enhancing paternity. Females of some

**Sex Role Reversal, Fig. 1** (a) *Neotrogla* sp. in copula. The female mounted on the male (the mating occurred on the roof of a cave). (b) Terminal abdomens of *N. curvata* in

copula, lateral view. U-shaped structure observed through the male's abdomen is the sclerotized part of the gynosome

*Rhamphomyia* species have fringed legs and/or inflated abdomens. These structures function as size-enhancing devices used to deceive males that would otherwise prefer to donate large-sized prey items to more fecund, large-sized females. Similarly, males of many bush cricket species (Insecta: Orthoptera: Ensifera) provide a large gelatinous mass (termed spermatophylax) attached to a spermatophore (sperm ampulla). The primary function of the spermatophylax is to protect the ejaculate. Sperm will evacuate the ampulla and move to the female sperm storage organ during the female's consumption of the spermatophylax. Females of *Hemianthus pallitarsus*, a species of ground weta, use an elbow-shaped structure to obtain this nuptial gift from males.

As illustrated above, sex role reversals are sometimes accompanied with drastic evolutionary changes in male and female morphologies. Male seahorses and pipefishes (Teleostei: Syngnathiformes: Syngnathidae) have a specialized pouch on the ventral side of the abdomen wherein females oviposit eggs using a specialized ovipositor. In these groups of fishes, only males care for eggs until they hatch. In some species, females are much more ornamental than their male conspecifics and compete with other females for access to males (Wilson et al. 2003).

Females of the cave insect genus *Neotrogla* (Psocodea: Prinoglarididae) use their

evolutionary novel penis-like structure, termed gynosome, for mating with males (Yoshizawa et al. 2014, Fig. 1). This “female penis” is ornamented with species-specific lobes and/or spine bundles, which are accommodated in specialized pouches of the vagina-like male genitalia. During copulation, which lasts 40–70 hours, voluminous and potentially nutritional seminal substances are passed from the male to the female through the gynosome. Since they live in dry, nutritionally poor caves in Brazil, gynosomes likely represent elaborate ways for females to exploit seminal foods from males. In accordance with this view, females of a related species with similar nuptial gifts (Psocodea: Trogiidae) compete for access to males. Moreover, *Neotrogla* females have also developed a specialized, evolutionary novel structure in their sperm storage organ that enables retention of two gifts simultaneously.

## Definition

Any phenotype is said to be sex-linked if the triggering gene for that phenotype is located on a sex chromosome (Morgan et al. 1915). Sex-linkage is the pattern of the allele expression and inheritance in association with the sex chromosomes of the individuals (Charlesworth 2017). For example, in humans, the term sex-linked phenotype generally refers to the characters that are influenced by the genes that are located on either X or Y chromosomes (Snell and Turner 2018).

## Introduction

Sex-linked phenotypes were discovered in the year 1910 by Thomas Hunt Morgan (an American geneticist) as white-eyed mutations in the “male” fruit fly (*Drosophila melanogaster*). Morgan was awarded a Noble Prize in Physiology or Medicine in 1933 for this discovery. He performed a series of experiments on fruit flies and reported that the gene that controls the color of the eyes in these flies is located on the X chromosome. He did a cross between a white-eye (mutant) male with a red eye (wild-type) female fly. In the first generation, all flies obtained were of red eye color as the white eye trait was recessive. The next cross between F1 generation males and females produced an F2 generation that was comprised of 3470 red eyed (both male and female) and 782 white eyed (only male) flies (Fig. 1). Sex-linked traits or genes are located on the sex chromosome, that is, X chromosome and Y chromosome in humans. The genes located on the X chromosome are called X-linked genes and, on the Y chromosome, Y-linked genes. In humans, Y-linked genes are transmitted only by males and have genotype XY. Contrarily, X-linked genes are transmitted by both males and females (Morgan et al. 1915).

## Characteristic Features of the Sex-Linked Phenotypes

- Mendel’s law does not apply to those genes that are completely located on either X or Y chromosomes.

**Sex-Linked, Fig. 1** Experiments/cross performed by TH Morgan

- Sex-linked inheritance is the inheritance of traits that are determined by the expression of genes located on the sex chromosomes (Raznahan et al. 2018).
- Sex-linked inheritance mostly occurs due to the X chromosome as compared to the Y chromosome.
- The genes located on the X chromosome are known as diandric and on the Y chromosome as holandric genes.
- The inheritance of X-linked genes and Y-linked genes from parents is called sex-linked inheritance.

### Sex-Linked Inheritance

Sex-linked inheritance is the passing of characters/alleles that are located on either of the sex

chromosomes (X and Y chromosome) from parents to the progenies. Therefore, the inheritance of X-linked traits is generally from mother to daughter, but Y-linked inheritance is from father to son only.

### Sex-Linked Disorder

Like autosomes, sex chromosomes are comprised of different genes that are required for the normal function. Functional alteration in these genes due to mutations leads to sex-linked disorders (Schurz et al. 2019). Mutations in Y chromosomes (Y-linked inheritance) are characterized by an alteration in male sexual functions and secondary male characters. For example, Y-linked inheritance disorder is comprised of

hypertrichosis that is characterized by growth of hair at the outside rim of the ear and Webbed toes that is characterized by web-like connection between second and third toes. Y-linked inheritance is carried out by the Y chromosome from father to his son only (Pavone et al. 2015). Similarly, the mutation in the X chromosome is defined as the X-linked inheritance. Some common sex-linked disorders are hemophilia (Lewis et al. 1963), red green color blindness (Wale et al. 2018), congenital night blindness (Le Pichon et al. 2013), Duchenne muscular dystrophy (Ward and Weber 2019), and Fragile X syndrome (Bagni and Zukin 2019).

In humans, sex-linked disorders can be categorized into X-linked and Y-linked disorders. X-linked disorders can be further divided into X-linked recessive and X-linked dominant disorders.

1. **X-linked recessive disorder:** X-linked recessive disorder is a mode of inheritance in which mutation in a gene located on the X chromosome that causes the phenotype is always expressed in males and females that are homozygous for gene mutation. The most common X-linked recessive disorders found in humans are Hemophilia (Hemophilia A and B) (Lewis et al. 1963) and color blindness (Le Pichon et al. 2013).
2. **X-linked dominant disorder:** X-linked dominance disorder is a mode of genetic inheritance, in which a dominant gene is carried on the X chromosome. X-linked dominant disorder is uncommon as compared to other Mendelian disorders, and females are mostly affected as compared to males. Females have two X chromosomes and do not show the transmission from father to son, and affected males are more severely affected than females. The X-linked dominant disorder is rare as compared to X-linked recessive disorder. The examples of X-linked dominant disorder are Fragile X syndrome, oral-facial syndrome type 1, and hypophosphatemic ricketsm (Bagni and Zukin 2019).
3. **Y-linked disorder:** Mutations in the genes that are located on the nonhomologous region of

the Y chromosome and directly pass from male to male may cause Y-linked disorder.

The list of some of the sex-linked disorders is as following:

| S. no. | Disorder                        | Symptoms                                                                                                                           | Sex-linked status                                                    |
|--------|---------------------------------|------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------|
| 1.     | Color blindness                 | The person is not able to distinguish between red or green or both color                                                           | Due to X-linked recessive genes (Yatsenko et al. 2016)               |
| 2.     | Hemophilia (Bleeder's disorder) | Pain, swelling, or tightness in joint and blood in urine or stool                                                                  | Due to X-linked recessive genes (Lewis et al. 1963)                  |
| 3.     | Rett syndrome                   | Leading to cognitive impairment in female                                                                                          | Due to X-linked dominant genes (Feldman et al. 2016)                 |
| 4.     | Double-cortex syndrome          | Intellectual disability, seizures, and behavioral problems                                                                         | Due to X-linked dominant genes (Sprugnoli et al. 2018)               |
| 5.     | Incontinentia pigment type 1    | Characterized by dermatological, ocular, dental, and neurological abnormalities                                                    | Due to X-linked dominant genes (Roberts 1958)                        |
| 6.     | Hypophosphatemia                | Electrolyte disorder in which there is a low level of phosphate in the blood                                                       | Due to X linked dominant genes (Cubillos Celis and Mena Nannig 2018) |
| 7      | Y-chromosome infertility        | Adult male produce immature sperm cells, fewer sperm cells, or sperm cells that are abnormally shaped or that do not move properly | Due to Y-linked disorder (Dhanoa et al. 2016)                        |

## Definition

Sexual antagonism (or sexual conflict) arises between the sexes when the evolutionary interests of males and females differ. Conflict can arise over the expression of a trait shared by both sexes, or over the outcome of reproductive interactions between males and females.

## Introduction

Sexual antagonism (or sexual conflict) arises between the sexes when the evolutionary interests of males and females differ (Parker 1979; Chapman et al. 2003; Arnqvist and Rowe 2005). It can be separated into two main forms, known as intralocus and interlocus sexual conflict, which differ in whether the target of selection is a single trait shared by both sexes, or different traits in either sex that interact to influence fitness, respectively. Conflict is the result of selective processes acting differently between the sexes, and may arise due to differences in the strength or direction of sexual selection, natural selection, or both. Sexual conflict ultimately arises when there are fundamental differences in reproductive roles between the sexes (Parker 1979). For example, female mammals carry young during pregnancy, and then suckle infants with milk until they are able to fend for themselves. Male mammals do none of this, and so have a much higher potential reproductive rate than females. Therefore, the best reproductive strategy for females is to focus on rearing healthy offspring, whereas for males it may be to contribute little to parental care, and instead father offspring with as many females as possible. These biological differences thus lead to very different optimal reproductive strategies. Recognition of these evolutionary conflicts of interest between the sexes allows us to explain a variety of adaptations in males and females, especially those relating to reproduction and parental care (Arnqvist and Rowe 2005).

### Intralocus Sexual Conflict

Intralocus sexual conflict arises when the optimal expression of a trait that is shared by both sexes differs (Arnqvist and Rowe 2005; Bonduriansky and Chenoweth 2009). For example, male elephant seals compete with each other for access to females, and so benefit from having a very large body size, whereas females do not. In other words, sexual selection acts to increase body size in males but not in females. This means that

selection on body size will act in opposite directions in either sex. This form of conflict is likely to be widespread, given that males and females have many shared traits with a common genetic basis. The outcome of such divergent selection depends on the extent to which gene expression is constrained between the sexes. If plasticity in gene expression is limited in some way, then the trait may be expressed at an intermediate, and thus suboptimal, level in both sexes (Bonduriansky and Chenoweth 2009). Alternatively, gene expression may become decoupled between the sexes, leading to sexual dimorphism. The fact that males and females are dimorphic in most species suggests that such differential expression is achieved often, and indeed we should expect it to evolve quickly when selection is strong. Therefore the evolutionary importance of intralocus sexual conflict remains unclear, and will ultimately depend on the importance of genetic constraints on trait evolution.

### Interlocus Sexual Conflict

Most theoretical and empirical work has instead focused on interlocus sexual conflict, which arises over the outcomes of interactions between males and females (Arnqvist and Rowe 2005). This form of conflict is most relevant when studying animal behavior, given that it arises primarily due to behavioral interactions between the sexes. Interlocus sexual conflict can arise in two ways (Arnqvist and Rowe 2005). First, conflict will arise for any sexual interaction for which the optimal outcome differs between the sexes. This includes conflict over aspects of the mating system such as mating rate, remating behavior, and parental roles. Second, conflict may arise whenever males and females need to cooperate during reproduction. This occurs for example in birds, in which both males and females provision young. Though both parents may benefit from sharing provisioning (as this should result in the greatest chance of offspring survival), each parent will also benefit if its partner does more work. This means that tasks previously seen as cooperative are more appropriately viewed as a form of negotiation,

with each parent trying to exploit the efforts of the other (Trivers 1972).

Interlocus sexual conflict is most commonly studied in relation to reproductive traits, and can occur before, during, and after mating. This includes conflict over mating frequency, fertilization, female remating behavior, and female reproductive rate. For example, in many species there is conflict between the sexes over whether females should be monogamous or polygamous (Arnqvist and Rowe 2005). For a male, the optimal outcome is for each female to mate only with him, as this will ensure that he fertilizes all of her eggs. However, females can often benefit by mating with multiple males during each breeding bout, for a variety of reasons. Therefore the optimal level of polyandry may be higher for females than for males. This conflict has led to the evolution of male adaptations in many species that prevent females from remating. These include behavioral adaptations such as mate guarding, anatomical adaptations such as mating plugs that block the female reproductive tract, and physiological adaptations such as male seminal fluid compounds which delay female remating (Arnqvist and Rowe 2005).

Another common form of sexual conflict arises over mating itself. Given that sperm are relatively cheap to produce, males can generally benefit most by mating with every female they encounter. In contrast, female reproductive rate is more restricted, and so females benefit most by mating with only the highest-quality males, either in terms of resource-holding potential or genetic quality. This has led to the evolution of female choice based on the assessment of male phenotype. However, sexual conflict means that selection on males will favor any adaptation that allows a male to circumvent female choice, either before or after mating. This conflict can explain a variety of antagonistic male mating behaviors, such as forced matings (Clutton-Brock and Parker 1995).

In some cases, sexual conflict may lead to one sex being directly harmed by adaptations in the other sex. For example, harassment and coercion by males may lead to the drowning of female waterfowl (Clutton-Brock and Parker 1995). Females may also be physically harmed by male

grasping structures, or by sharp spines found on the male genitalia (Arnqvist and Rowe 2005), and in some species this harm may significantly reduce female fitness and fecundity (e.g., Dougherty et al. 2017). In these cases harming of females does not seem to benefit males directly, but rather arises as a by-product of selection on male traits that increase male mating or fertilization success (Morrow et al. 2003). In such species, selection on females to evolve counter-adaptations to reduce harm is particularly strong. Examples of such counter-adaptations include the thickened reproductive tracts and increased immune activity seen in female seed beetles (Dougherty et al. 2017).

Males and females also have to interact when raising offspring, and this leads to a variety of conflicts between the sexes over parental care strategies and behaviors (Trivers 1972; Arnqvist and Rowe 2005). Though both parents have equal relatedness to the offspring, and so would benefit equally from offspring survival, parents are generally unrelated to each other. This means that each parent can gain by allowing the other to contribute more to care: the “cheating” parent will then have more resources available to allocate to future breeding attempts (Trivers 1972). Conflict can thus arise over the amount of care each sex provides in monogamous species. Theory predicts that biparental care is evolutionarily stable when reduced care by one parent leads to increased care in the other, but not so much that it completely compensates for the reduction, a pattern which is supported by experimental data (Harrison et al. 2009). There is also conflict over the optimal reproductive strategy of each sex in relation to parental care. This is because males usually benefit from mating with many females, and getting someone else (either the female or another male) to rear his offspring. In contrast, females usually gain most from the male staying and exclusively helping her with caring. This conflict has for example led to the evolution of female behaviors that prevent males from soliciting extra-pair matings, such as showing high levels of aggression to rival females, or to males when they exhibit display behaviors (Arnqvist and Rowe 2005).

## Sexually Antagonistic Coevolution

One important consequence of sexual conflict is that any adaptation that moves a shared trait or outcome closer to the fitness optima of one sex necessarily moves it away from the fitness optima of the other. This leads to strong selection on the other sex to resist or counteract such change. This results in a process called sexually antagonistic coevolution (SAC), whereby males and females are locked in an evolutionary “arms race,” with adaptations which increase fitness in one sex being countered by adaptations in the other (Parker 1979; Arnqvist and Rowe 2005). SAC can be distinguished from other forms of coevolution (such as the Fisher runaway process) by the fact that it is driven directly by a reduction in fitness in the opposite sex. However, SAC has been historically difficult to detect. This is because during conflict selection will strongly favor counter-adaptations, which should therefore evolve rapidly. This means that in most species, even those characterized by strong sexual antagonism, males and females should be at a fitness equilibrium, with the fitness costs of conflict essentially hidden from view (Arnqvist and Rowe 2002, 2005). However, this problem can be overcome by considering male and female traits simultaneously, allowing signs of SAC to be detected when there is a relative imbalance in male and female trait expression (Arnqvist and Rowe 2002; Dougherty et al. 2017). SAC has the potential to generate rapid phenotypic divergence, and has been suggested to have driven the evolution of elaborate behavioral and anatomical traits in a range of species.

## Conclusion

The development of the theory of sexual conflict in the 1970s revolutionized our understanding of how males and females interact with each other, and how reproductive behavior and anatomy may evolve. It is now clear that male and female interests are rarely exactly aligned, and that there may be conflict between the sexes at almost all stages of reproduction. Only by recognizing the presence

of conflict can we understand the evolution of a variety of male and female behaviors, including mate choice, polyandry, and parental care. More broadly, this recognition of the importance of conflict has required a change in perspective when thinking about sexual interactions. Reproduction is now more rightly seen as a careful negotiation between two independent and self-interested parties, rather than as a completely cooperative endeavor.

Complex of differences in body size (sexual size dimorphism, SSD), shape, traits, color, and parasitic load between males and females of the same species.

## Introduction

Sexual dimorphism has been the subject of wonder and scientific studies for centuries, being present in most animal species since prehistoric times. According to Aristotle (fourth century BC), differences in the semen temperature at the time of copulation resulted in sexual dimorphism, with hot semen generating males and cold semen generating females. In the *Historia Animalium* (IV, 11), Aristotle reported that in all the species where differences between males and females occur, nature has clearly differentiated the character of females from that of males. Aristotle claimed that females are less muscular, have less sturdy joints and finer hair, moist flesh, thinner legs, and more delicate feet with respect to males, and their voice is higher-pitched. As to bones, Aristotle stated that females have smaller skulls, tighter faces, thinner necks, weaker chests, and minute femurs. Differences in morphology are associated with different behavior, from which Aristotle derives a judgment on the inferiority of the females compared to males. This idea of sexual dimorphism promoting the superiority of males has been kept throughout ancient times and the Middle Ages at least. In modern times, Charles Darwin suggested that sexual dimorphism may result from sexual selection when individuals of one sex compete for access to members of the other sex (Darwin 1871/1958). In *The Descent of Man*, he exposed the theory of sexual selection, to explain the evolution of secondary sexual characters (e.g., weaponry, ornamentation), commonly developed in male vertebrates, whereas rare in females. These characters do not increase survival probabilities but have been evolved to intrasexually compete for reproduction. This evolutionary process was called “sexual selection” (Darwin 1871/1958). The degree of

sexual dimorphism in structures and coloration is strictly related to sexual selection (Ralls 1977). Color differences might be so marked that first taxonomists classified as different taxa widely dimorphic species, e.g., the mallard *Anas platyrhynchos*. Sexual dimorphism may also occur for body size. After Darwin, a plethora of research works has confirmed the evolution of secondary sexual characters in males, whereas attention towards mechanisms triggering the evolution of secondary characters in females has been only recently developed (Clutton-Brock 2009).

### Anisogamy and the Molecular Development of Sexual Dimorphism

Physiological and behavioral differences between males and females depend on the different sizes and shapes of gametes, i.e., “anisogamy,” which occur to optimize individual fecundity. Anisogamy is a basic concept within the topic of sexual dimorphism, and it may explain phenotypic differences between sexes. Usually, females rear the offspring and have a limited reproductive period with respect to males, thus representing a limiting factor in the reproductive success rate of males in a species (Fritzsche and Arnqvist 2013). According to the Bateman’s principle, males and females should select for different traits in partners, which therefore should develop intersexual, species-specific phenotypic differences over many generations (Fritzsche and Arnqvist 2013). The concept of monogamy implies exclusivity in mating, i.e., one male and one female will mate only with each other. In monogamous species, both parents participate in parental cares (Trivers 1972; Clutton-Brock and Vincent 1991) and monogamous species are often sexually monomorphic (Kleiman 1977; Mori and Lovari 2014). By contrast, in most dimorphic species (i.e., polygynous or polyandrous), both genders select mates according to the desirable traits of the available phenotypes of potential mates (Fritzsche and Arnqvist 2013). Sexual dimorphism is not restricted to the genital tract and secondary structures but it affects many structures and functions not directly concerned with reproduction. Sexual

dimorphism is known to be regulated by genes located in sexual chromosomes (Haqq and Donahoe 1998). Most differences are observed on adult individuals and are linked to the production of sex hormones involved in growth, metabolism, endocrine activity, life expectancy, and behavior (Glucksmann 1974). As to body size, female-biased SSD is the common pattern in invertebrates and cold-blooded vertebrates, whereas males are the larger sex in most mammals.

### Sexual Dimorphism in Invertebrates

Females are the larger sex in most invertebrates, since often they take longer to develop in respect to males; selection implies a positive correlation between female size, fecundity, and egg production. This correlation has been proposed to be the major force leading to female-biased SSD.

SSD is common among Echiurid worms (e.g., *Bonellia viridis*), where dwarf vagile males show planktonic behavior to reach large, sedentary females (Vollrath 1998). In most free-living nematodes, sexual dimorphism is not evident, but, in some parasitic groups, females are larger than males, to produce more progeny and to facilitate reproduction to small, vagile male. Cyst and root-knot nematodes exhibit the most marked sexual dimorphism, with roundish females and vermiform males (e.g., *Globodera* spp.).

Sexual dimorphism is rare among mollusks. By contrast, in argonaut cephalopods *Argonauta* spp., external sexual dimorphism is marked, with males reaching only 1 cm in size, and females larger and secreting a fragile laterally compressed shell (Vollrath 1998).

SSD is common in Arachnida, with males smaller than females. Selection for small male size in Arachnida is mainly influenced by sexual cannibalism and differential mortality rates (Vollrath 1998; Prenter et al. 1999). Many males of Salticidae have bright colors, elaborate ornamentation, and show sexual color dimorphism: sexual dimorphism in ultraviolet perception also occurs.

Among Crustacea, mate-guarding males of some amphipods develop structures for fighting,

absent in females. Sexually dimorphic appendages and structures engaged in reproduction are present in male copepods. In some decapods, females have larger abdomen for egg brooding, and males have larger carapaces and more developed appendices (e.g., chelae), also involved in the intrasexual competition for mating (e.g., Stein 1976). For instance, males of *Uca* spp. have one large chela used for mating displays, sound production, and intraspecific aggression.

Myriapoda are poorly studied for sexual size dimorphism, although sexual differences are known in body size of over half known taxa (Cooper 2014).

Sexual dimorphism occurs in most insect species, with female-biased SSD being predominant (e.g., Coleoptera, Odonata, Orthoptera, Phasmatodea). Often, females develop through a higher number of instars than males.

Coleoptera represent the greatest number and diversity of sexually dimorphic insects. Sexual dimorphism ranges from indistinguishable to differential enormous size and shape (Kawano 2006).

Conspicuously dimorphic species show highly developed male traits such as horns (Scarabaeidae: Dynastini, usually confined to the largest males), mandibles (Lucanidae; Cerambycidae), and tibiae (Scarabaeidae: Euchirinae) (Kawano 2006). These structures are used as weapons for intrasexual aggression and for mating purposes.

In Diptera, sexual dimorphism is not so evident as in Coleoptera, but wing length is greater for highly mobile females. Sexual dimorphism in the compound eyes reaches extreme levels in Bibionidae family, with males having larger eyes to detect and catch females on the wing. In mosquitoes and moths, males have plumed antennae to intercept the female pheromones. Butterflies (Lepidoptera) show a variety of sexual dimorphism, including SSD and color dimorphism, with males often brighter and smaller than females (Rutowski 1997).

## Sexual Dimorphism in Vertebrates

Sexual selection has been considered by postmodern and contemporary scientists as a fundamental

but insufficient factor by itself to explain sexual dimorphism in vertebrates (Clutton-Brock and Vincent 1991). Mating system, parental investment, diet, habitat selection, reproductive success, and population density have also been reported to be pivotal factors shaping morphological differences between males and females of a species (Ralls 1977; Hedrick and Temeles 1989).

*Chondrichthyes and Osteichthyes.* In sharks, a female-biased SSD has been observed in many species, with individuals reaching larger sizes at the highest latitudes. Differences in habitat selection and spatial behavior have also been reported (Mucientes et al. 2009). Cephalic bulge of *Sphyrna tiburo* and elongated intermittent organs observed in similar species have been developed for intrasexual competition. Dental sexual dimorphism is well documented in many Batoidae, showing a stable molariform morphology in females and a periodic shift in male dentition to a recurved cuspidate form during the breeding season. A similar form of dimorphism has been described for dogfish. This is due to the fact that these species usually bite during the courtship; sharp teeth provide males with an increased fitness potential and reproductive success. Among Osteichthyes, SSD is very widespread; males are usually smaller than females, except for those species where males fight for reproduction and participate in offspring care. Highly polygynous species shows males larger up to 60 times a female, or possessing longer fins; larger males may mate with a higher number of females. In Osteichthyes, large males also inhibit the growth of females and control environmental resources. Ornamentation in males or females is present only in few species and directly linked to complex courtship behavior and sexual selection (Amundsen and Forsgren 2001).

*Amphibians.* In Amphibians, females usually attain larger body sizes than males, to increase their fecundity and because males usually do not live enough to reach large sizes (Shine 1979). Furthermore, smaller males are agile and may reach females easier than large ones. Males are larger only in those species where access to reproduction is mediated by intrasexual competition, as females prefer to mate with large males (Howard

1978). In these last cases, Anuran males also may develop spines and tusks (Shine 1979). Furthermore, vocalizations used by male frogs to call for females are pivotal for reproductive success in frogs and toads (Shine 1979). Among Urodeles, the dorsal crest of crested newts *Triturus* spp. is a sexually selected trait evolved in correlation with a complex courtship behavior.

**Reptiles.** Polygyny has been observed in a great number of reptile species, and polyandry is also common even if it may have been underestimated (Cox et al. 2007). Dimorphic colorations and ornaments have been observed in lizards, as well as sex-related behavior. Sexual-size dimorphism is very common among reptiles (Cox et al. 2007). In lizards and crocodiles, it is mainly male-biased (with males exceeding females by up to 50% in length), whereas in snakes and turtles it is always female-biased (with males exceeding females by over 50% in length), with the exception of all the viperids, many elapids and colubrids, as well as of testudinids (Cox et al. 2007). Across reptiles, sexual dimorphism seems to decrease with increasing latitude (Cox et al. 2007). Evolution of sexual dimorphism in reptiles may have been promoted by sexual selection for large and bright-colored males, fecundity selection for large females, as well as by natural selection to reduce resource competition (Cox et al. 2007).

**Birds.** Sexual dimorphism is widespread among birds and it can be shown in plumage, voice, or size differences. Plumage and voice dimorphisms are related with cryptic female choice, whereas size dimorphism is related to intrasexual competition and mating systems. Plumage dimorphism is associated with mating system, being much more present in polygynous and promiscuous species. In those species, males show often bright plumages or ornamentations (e.g., long tails, caruncles). Bright plumages are related to a good health status and a high fitness; therefore, bright males are selected by females for reproduction (Dunn et al. 2001). Despite being highly visible to predators, the cost of natural selection is still lower than the benefits by sexual selection in colorful males. In polyandrous species (e.g., Charadriidae and

Jacaniidae), females are larger, brighter, or richer in ornaments, as they compete for breeding opportunities (Clutton-Brock 2009). Differences in plumage may reflect differences in behavior: for instance, females of eclectus parrots *Eclectus roratus* are bright red, whereas males are green as they search for food in the canopy and need to be camouflaged to escape from predators. Monogamous species may show SSD, mostly related to testes masses resulting in sperm competition (Dunn et al. 2001). Where sexual-size dimorphism occurs, it is mainly male-biased, with the exception of raptor birds, skuas, and hummingbirds, where females are larger. Larger males are better competitors than smaller ones and produce successful offspring (Dunn et al. 2001): they also better cope with migration and thus have a higher fitness and reproductive success. In raptors, monogamy occurs and both parents take care of the offspring; therefore, intrasexual male-male competition should not be required. While females lay eggs and take care of *pulli*, males have to search for food, thus being advantaged in being smaller to move among dense vegetation.

**Mammals.** Over 94.5% of mammalian species are polygynous (Kleiman 1977), with males competing for females using antlers (e.g., in cervids), horns (e.g., in bovids), and canine teeth (e.g., in carnivores, suids, musk deer, and baboons), and investing little in offspring (Ralls 1977). SSD is the commonest form of sexual dimorphism among mammals (observed in over 4000 living species: Ralls 1977). In most cases (about 85%), male mammals show a larger body size with respect to females (in carnivores and ungulates), which may be the result of intrasexual competition (Ralls 1977). This is primed by testosterone production, which promotes body growth (Glucksmann 1974). Female-female competition for males and polyandry are uncommon among mammals (Clutton-Brock 2007). Thus, females are rarely the largest sex (Ralls 1976, 1977), although large females may produce larger litters and can also better defend offspring from cannibalistic males, which explains why they are the larger sex in some species (Ralls 1976; Clutton-Brock 2009).

Besides selection for a larger body size, weapons and body size itself can be emphasized through the use of attention-guiding adaptations (e.g., contrasting colors; presence of a ruff, a mane, or a beard; horns and antlers), which thus become secondary sexual characters, also used in sexual selection.

The lion *Panthera leo* shows an association between coat color, dominance, and reproductive success: dark maned males are dominant and more attractive to females than those with a lighter colored mane (West and Packer 2002). In the hot temperatures of African savannah, mane color may work as a honest signal of physical vigor, as dark manes attract solar radiation thus making these males suffer higher surface temperatures and other costs, which implies a greater stamina.

On the other hand, the high altitude, mountain-dwelling golden-ruffed Himalayan tahr *Hemitragus jemlahicus* males are not only dominant over dark-ruffed ones, but they also monopolize nearly 90% of copulations (Lovari et al. 2009), which suggests an inverse mechanism to reach the same scope: reproductive success of the fittest.

## Sexual Dimorphism in Humans and Other Primates

In spite of poor information on determinants of sexual dimorphism in the second half of the nineteenth century, Charles Darwin developed a few insights on the effects of sexual selection on the evolution of dimorphism in humans. These insights are still valid and have been supported with new evidence.

Among most primates, competition between males to access oestrus females is usually intense, which tends to favor selection towards male larger size and distinctive color patterns/body structures in direct and indirect forms of aggression. This is most apparent with polygynous species, such as the gorilla and the baboons, as well as with promiscuous ones, as the chimpanzees. A slightly larger SSD and different body morphology may also be recognized in primates with multi-male/multi-female mating systems.

There are a few primate species which are normally monogamous (obligate monogamy, i.e., depending on dispersion pattern and quality of main food resources which make it impossible for a male to defend a territory larger than one sufficient to host only one female with offspring), for example, gibbons and owl monkeys. These monogamous species can become bigamous when/where resources are abundant and not so dispersed; thus, because of that, their territories can shrink to a defendable size and still contain enough food for an additional female with offspring. These monogamous species show very little sexual dimorphism, if any.

*Homo sapiens* shows an adult male-to-female body weight of about 1.1–1.2; on average, males are taller than females, with a ratio of 1.06; they are also more muscular, have larger heart and lungs, a greater number of red cells in blood, and a beard (Dixon 2009). Also, males with a broad chest and shoulders, narrow hips, and a muscular torso tend to be considered attractive partners by females, so that sexual selection comes into play. Conversely, females invest more in the production and storage of fat, mainly deposited around buttocks, hips, thighs, and breast, as a result of estrogen action, when they become mature reproductively (Pond 1998). In fact, fat reserves are crucial for reproduction and it makes sense their positive selection in evolutionary terms, as they are honest signals of reproductive potential. There are quite a few other signs of sexual dimorphism in *Homo sapiens*, relevant to skin color, craniofacial traits, and voice pitch, some of them dependent on differential hormone actions during development. All these features make the human species a remarkably dimorphic one.

Sexual dimorphism in cranial and facial features of the earliest australopithecines was quite strong, remaining little changed in *Homo habilis*. Conversely, it decreased in *Homo erectus* and *Homo neanderthalensis*, while still remaining well above the modern human range, which shows a reduction of sexual dimorphism perhaps because of convergence in the requirements of male and female roles (Freyer and Wolpoff 1985). Most likely, *Homo sapiens* evolved from a primarily

polygynous – thus, strongly sexually dimorphic – nonhuman primate precursor, with the earliest members of the genus *Homo* to some degree polygynous (Dixon 2009).

## Sexual Identification

Luciano Augusto Weiss and Alex Pires de Oliveira Nuñez  
Laboratory of Biology and Freshwater Fish Culture, Federal University of Santa Catarina, Florianópolis, Brazil

### Synonyms

[Sex check](#); [Sexing](#); [Sexual classification](#)

### Definition

Sexual identification allows the classification of animals as males, females, or hermaphrodites and the intersex condition and can be performed in a simplified way for species with apparent sexual organs and/or marked differences between the sexes, known as sexual dimorphism, or through specific sexing methods for species that do not have such differences.

### Description

Identifying sex in animals may seem, at first, a simple and straightforward task. In fact, some species have apparent sexual organs or marked morphological characteristics, a condition known as sexual dimorphism, which makes visual distinction between the sexes simple. On the contrary, there are species in which males and females present extremely similar external characteristics, so no significant differences between the sexes can be perceived, making the application of

sexing methods necessary for sexual identification.

Sexual dimorphism occurs in many groups of living beings: protists, plants, and animals. The function of these differences is usually related to the reproductive process; the different characteristics are used to conquer or to fight for a partner.

A difference in size between the sexes is the prevailing characteristic in the majority of animals that show sexual dimorphism (Blanckenhorn 2000). Ornamentation is another common type of dimorphism and is often observed in many species of birds and reptiles (Johnsen et al. 2003). In most species, sexual dimorphism becomes more evident as organisms grow, which makes sexual identification difficult in the early stages of development. In birds, which have internal reproductive organs, confusion in defining the sex of young individuals is common.

Most fish species have a well-defined pattern of sexual development as female or male, which characterizes gonochoristic species, although a small fraction of species is hermaphroditic. Recognizing sex in most species of teleost fish is a difficult task, and to facilitate the sexing process, it must be performed during the reproductive period.

Sexual dimorphism is also present in fish, but in most instances, it is expressed only during the reproductive period. Species that exhibit transient dimorphism develop forms of sexual attraction, such as protuberances, color change of the scales, and emission of sounds, during the period of reproduction only. However, permanent dimorphism evidences, such as differences in size, differences between the sexes at sexual maturity.

The biological process that determines the development of sexual characteristics of an organism is called sexual determination. Throughout the evolution of the species, several mechanisms of determination and regulation of sexual development have been generated, creating a complex system of sexual determination. In most cases, sex determination is genetic, through sex chromosomes whose action is complemented by a wide variety of regulatory mechanisms. In addition, some species have a chromosomal basis involving both monogenic and polygenic systems, located in the autosomal chromosomes and in the sex

chromosomes and regulated by different genetic and/or environmental factors.

The various mechanisms of sex determination began to be elucidated after 1930, through studies that identified different models involving sex chromosomes. These studies have shown that most mechanisms are genetic, involving sex chromosomes of the XY, XO, ZW, and ZO systems. In some cases, sex may be determined by haploid-diploid systems or by environmental and/or social variables, such as the surrounding temperature or the dominance of males or females in certain species. Usually in animals, the distinction between the sexes occurs through chromosomal differences, with one sex presenting two distinct sex chromosomes (heterogametic) that produce two types of different gametes and the other sex presenting two of the same sexual chromosomes (homogametic), which produce a single type of gamete.

In insects, dimorphism in the sex chromosomes can be cytologically distinguished. In the order Lepidoptera, which comprises all the insects popularly known as butterflies and moths, the sex chromosomes are designated as W and Z, with the W chromosome associated with female characteristics. The influence of temperature is crucial in the determination of sex in some species of this order, favoring the generation of a specific sex according to the available environmental resources, which increases the probability of reproduction.

In *Drosophila melanogaster* (order Diptera), a highly studied laboratory model, development as female or male is related to a change in a so-called lethal sex gene (*Sxl*) in response to the balance between the number of sex chromosomes X (female sex) and the number of autosomal chromosomes (male sex). In this case, the Y chromosome present in the males does not influence the sex determination. Depending on the balance between these chromosomes, sterile male animals (metamales), intersex animals (animals with male and female characteristics), or female animals with developmental problems (metafemales) may occur (Manolakou et al. 2006).

In other insects, such as bees and ants, the haploid-diploid system is seen, in which the

male is haploid ( $n$ ) and the female is diploid ( $2n$ ). Males, generated from unfertilized eggs (parthenogenesis), are called drones and have only one chromosome of maternal origin. Females are heterogametic, originating from an ovum fertilized by a spermatozoon.

In reptiles (order Squamata), several patterns of sexual determination have been found. The snakes present a ZZ/ZW pattern of sex chromosomes and lizards have a ZZ/ZW or XX/XY system. In contrast, there are species of turtles and crocodiles that do not have distinct sex chromosomes or genes related to sex determination. In these cases, the temperature of the environment during a specific period of egg incubation is preponderant in determining sex. In this process, the enzyme aromatase catalyzes the conversion of androgen hormones into estrogen, influencing the differentiation of gonads. At high temperatures, the aromatase has high activity, differentiating the gonads into ovaries, and in lower temperatures, activity is reduced, leading the gonads to differentiate into testicles.

Although in amphibians the sexual determination is genetic, both sexes are heterogametic and are not influenced by the environment or polygenic conditions. In some species, spontaneous sexual inversion occurs, which produces animals genotypically and phenotypically discordant in relation to sex. Sex chromosomes can be of type ZZ/ZW or XX/XY.

In birds, the Z and W chromosomes determine sex, with females being heterogametic (ZW) and the males homogametic (ZZ). The Z chromosome has a uniform size in all species, but the W chromosome varies in size in most of them. Only in the ratite birds (Struthioniphormes), the sexual chromosomes are morphologically similar to the autosomes, with little difference in size.

Fish exhibit a wide variety of mechanisms of sexual determination and patterns of sexual differentiation. In many species, the determination of sex depends on a chromosomal basis that involves monogenic and polygenic systems located in the autosomal and sexual chromosomes, in addition to being influenced by different environmental factors. In fish, the genotype can affect the

differentiation to testis or ovary, termed Genotypic Sex Determination (GSD), with or without the participation of chromosomes in the definition of each sex (ZZ in males and ZW in females or XY in males and XX in females). Environmental factors, including photoperiod, social environment, and temperature, may also influence sex determination in some species of fish, for which two terms with equivalent meaning are also used: environmental sex determination (ESD) and temperature-dependent sex determination (TSD).

In placental mammal species, the females usually have XX sexual chromosomes, whereas males present XY. The marsupials show the smallest Y chromosome among mammals, but testicular formation does not control the remainder of the sexual differentiation, because the formation of the scrotum and the mammary glands occurs before gonadal differentiation and is controlled by genes located on the X chromosome.

Due to the complex systems of sexual determination and differentiation in animals and to the absence and/or late presence of sexual dimorphism in many species, different methods have been developed for the identification of sex. The emergence and improvement of these methods of sexing are linked to the importance of identifying sex in certain situations, that is, advancements tend to occur proportional to the environmental and/or economic interest involved.

Sexing birds is difficult because at least half of bird species do not show sexual dimorphism and when it is present it is usually very subtle, occurring only at sexual maturity. The sexing of the true parrot (*Amazona aestiva*), a bird that does not present sexual dimorphism, can be performed by pubic palpation. This method requires experience to perceive the separation between the bones of the pubis, where a greater spacing may indicate the egg passageway. However, other, more accurate, methods are also used, such as the analysis of sex chromosomes, endoscopy (an invasive method requiring sedation), and hormonal analysis (levels vary according to sex).

The most precise methods for sexual identification are genetic ones, based on the application

of modern techniques of molecular biology. These involve the direct analysis of genetic variations and can be performed on chromosomes or on DNA and RNA sequences.

The best-known methods involve the visualization of the sex chromosomes from the karyotype, the set of chromosomes of an organism, with cytogenetic techniques that allow visualization during cell division through conventional staining such as giemsa or hematoxylin/eosin. In these methods, the objective is to visualize the chromosomal pair responsible for determining the genetic sex, and due to their precision, they have been used to test the accuracy of other methods of sexing.

Another way to perform sexing is to detect a Y chromosome-specific DNA sequence after amplification using the polymerase chain reaction (PCR) technique. Sexing by the PCR technique can be applied to various tissues or cells and, as the genetic sex is determined by the presence of the Y chromosome in mammals, the detection of a specific gene from this chromosome is the basis for this technique. Several such genes have been described, of which the SRY (sex-determining region Y) is best known as a testicular differentiation factor (Bronwyn and Andrew 2002).

In birds, the sex chromosomes Z and W have the genes CHD-Z and CHD-W (CHD: chromohelicase-DNA-binding), respectively, and through the PCR technique, it is possible to perform sexing by gene detection.

In fish, research into the genetic identification of sex uses homology to genes involved with sexual determination found in other species. The genes involved in the process of sexual development can be classified into functional groups, with genes involved in the development of the bipotential gonad and genes involved in determining and differentiating the sex of males or females.

Measuring levels of steroid hormones has also been investigated as a method of sexing in fish and has the advantage of being a less invasive technique when compared with laparoscopy or gonadal biopsy. The measurement of these steroids is performed with great precision at the plasma level, mainly through enzyme-linked

immunosorbent assay (ELISA) or radioimmunoassay (RIA), which identify the variations of sexual steroids according to each sex.

## Sexual Selection

Elena Racevska and Sam Hyde Roberts  
Department of Social Sciences, Faculty of  
Humanities and Social Sciences, Oxford Brookes  
University, Oxford, UK

Sexual selection is an aspect of natural selection specifically acting on an organism's ability to obtain a mate, to engage in a successful copulation with a mate (intersexual selection), or to compete with members of their own sex for access to members of the opposite sex (intrasexual selection). This selective preference is often manifested and most visible in the form of enhanced physiological characteristics within the competing sex and may take the form of heightened vigor, increased attractiveness, or in the intensification of offensive physiological adaptations. Similarly, the selective force can also act in a much more subtle manner, affecting gametal development and competition. However, the ultimate direction of the selective force is to improve the competitiveness of an individual and improve its probability in securing a mate and passing on its genes to the next generation. Much like in the case of natural selection, sexual selection also requires variation at the level of the gene, with some of the genetic variation ensuring advantages for the individual organism that possesses them. Crucially, sexual selection only acts after the animals have entered the age of reproduction and are sexually mature.

## Historical Development of the Concept of Sexual Selection

### Charles Darwin and Alfred Russel Wallace

The concept of sexual selection was proposed by Charles Darwin in his publication “*On the Origin of Species by Natural Selection* (Darwin 1859) and further developed in *The Descent of Man, and Selection in Relation to Sex* (Darwin 1871). Darwin saw in sexual selection an explanation for the evolution of nonadaptive characteristics that only seemed to facilitate organisms’ reproductive success, often at the expense of their survival. He believed this type of selection depended on the struggle between the competing sexes (most often the males) for access to the choosing sex (most often the females). Darwin identified two distinct scenarios: one in which the males aim to drive away or kill their immediate rivals and the other in which they act in such a manner as to win over the females and eventually copulate with them. In the first scenario, the successful male is granted access to the female or females, while in the second instance, the female has an active role in selecting the mate.

Darwin noted that sexes differ not only in their primary sexual characteristics – their reproductive organs – but also in the secondary sexual characteristics. Males often possess features that help with securing a mate and facilitate the act of reproduction, while females possess features that help with the nourishment and protection of the offspring. In addition to these traits, Darwin also recognized features that are seemingly independent of the primary sexual organs but that must play an important role in sexual selection – body size (and in some species of insects – body structure), strength, ornamentation, and coloring, to name a few examples.

If the sexes differ in their “habits of life,” morphological differences are a result of sexual selection. If their habits do not differ, the more developed organs most often aid the intrasexual competition, giving one organism (most often a male) an advantage over another.

In the majority of species, male individuals mature observably faster than female individuals. The reason for this, Darwin wrote, could be in the

morphological and developmental differences of the sex cells – females are much larger and require not only more time but also a greater nutrition in order to develop. Males are also more eager to seek a mate, with the preparations for this endeavor starting well before the potential mates are even available. For example, the males of many migratory species arrive early to established breeding areas, thus ensuring sufficient time for intrasexual competition to take place over territory and therefore over the possession of females. The secondary sexual characteristics therefore more frequently develop in males, but exceptions exist, particularly in birds. It has been suggested that in cases when the sexes resemble each other, a process of double (mutual) selection could be at play. In such a setting, both females and males would show a preference for more attractive and vigorous individuals of the opposite sex. Darwin deemed this highly improbable, since in most cases males show readiness to mate with any female. Darwin also believed that the sexual dimorphism is closely related to polygamy.

Throughout his publications, Darwin provided a diverse array of examples of secondary sexual characteristics and inferred that they had evolved as a result of sexual selection. His numerous examples and accounts of sexually reproducing species across many different animal classes range from mollusks and crustaceans to various orders of insects and vertebrates – fish, amphibians, reptiles, birds, and mammals – including humans. In the latter case, he concluded that sexual selection was likely of a much higher importance during the earlier stages of hominid evolution, even suggesting that sexual selection pressures were the likely means of the differentiation observable within the human races. In his opinion, each race has been perpetuated by the differences in preferences for particular physical features, which neither serve a purpose nor ensure any advantages (other than an increased likelihood of being selected as a mate) in daily life. In addition to the physical properties, Darwin also held sexual selection responsible for the differences in character and mental capacities. He declared men the more capable of the sexes – a bid he supported with an argument of the higher

number of men of great eminence in different areas of science and art, failing to account for the role of different socialization pressures and social expectations of women and men.

Unlike Darwin, Alfred Russel Wallace was not a firm advocate of sexual selection. He considered it improbable that variables such as the superior ornamentation of males would be enough to ensure female preference and thought the differences would have been too slight to drive such expression. Furthermore, he believed that physical competition between males would yield a different set of results than would occur from female preference. In his opinion, physical differences, such as the length of a flight feather or the hue of a bird's plumage, were typically not associated with strength and the health of an individual (Wallace 1892). In addition, Wallace considered many species to be of insufficient cognitive capacity to recognize the individual possession of aesthetic sexual preferences similar to those of humans, which, in his opinion, belong to the "spiritual nature," rather than the "animal nature."

### Ronald Fisher

One of the biologists who refuted Wallace's notion of sexual selection was the English evolutionary biologist and statistician Ronald Fisher. In his 1915 paper "The evolution of sexual preference," Fisher rejected Wallace's conclusion that animals do not show mate preferences based on their aesthetic appeal, emphasizing that their motives are unknowable to humans. He further stated that if this was the case, then the function of a species' secondary sexual characteristics, as well as their elaborate courtship displays toward potential mates, would also axiomatically remain unexplainable. Fisher then raised the question of the evolutionary origins of such "artistic faculties," if they are solely a characteristic of humans and not a facet of wider evolution (Fisher 1915). Fisher argued that animals' struggles are not confined to merely producing and rearing offspring but are also an investment in their later and prolonged success. This hypothesis places additional pressure on an individual's mate choice, as the selecting sex (most often females) needs to select a member or members of the opposite sex that are

more likely to produce viable and successful offspring. He added that mate preferences are not universal but have instead evolved in accordance with each species' unique biological requirements. Fisher also recognized three separate phases in the development of secondary sexual characteristics. Firstly, a trait must be favored by natural selection for its initial origin. Secondly, the trait may then become independent of natural selection, maintained predominantly by sexual selection. In some cases, the characteristic may even oppose the pressure imparted by natural selection and present a costly disadvantage to the individual. At this stage, the trait must greatly contribute to the individual's sexual attractiveness and further outweigh any costs and disadvantages it imparts on natural selection. In the final phase, natural selection and sexual selection balance each other out and reach a state of equilibrium, which may be eventually interrupted by the rise of other features' importance. Fisher argued that mate selection carries an even greater importance among humankind. Aesthetic appeal remains important, but it does not adequately represent "human personality," which he deemed an extremely important factor in mate choice. Fisher explains that human mate choices have comparably more long-term consequences than do the choices of many animal species. Fisher proposed that heightened intelligence has enabled humans to rise above the simple assessment of specific characteristics and allows for a more holistic and fuller appreciation and understanding of a prospective mates' value. While beauty is superficial, morality is fundamental, and according to Fisher, it is the "ultimate judgment of human value" (Fisher 1915).

In 1930, Fisher published *The Genetical Theory of Natural Selection*, wherein he combined Darwin's theory of natural selection with Mendelian genetics. Fisher rejected the idea of blending inheritance, the most widespread model of inheritance during the nineteenth century, according to which offspring inherited a blended version of their parents' traits. He argued instead in favor of particulate inheritance, which allowed for genetic variance. He proposed a principle of runaway selection (also known as Fisherian runaway),

which explains the evolution of sexually dimorphic traits appearing in exaggerated forms in males as a result of directional female choice. Building on the ideas of the importance of accounting for the offspring's probable future success, the importance of which he recognized in his 1915 paper, Fished proposed the so-called sexy son hypothesis. Herein he stated that the ideal mate, from the perception of females, is one whose genes will produce male offspring with the best chance of reproductive success. If females choose physically attractive males as mates, their offspring will more likely also be more attractive. As other females will share their preference, they will prefer their attractive sons and thus ensure their high reproductive success. The same principle holds for heritable behavioral traits.

### Angus John Bateman

The field of evolutionary biology was further advanced by the English botanist and geneticist Angus John Bateman. Bateman's main contribution to sexual selection research was his 1948 study of the common fruit fly (*Drosophila melanogaster*), inspired by Darwin's notions on sexual selection. Bateman conducted six series of experiments, for which he created multiple, isolated inbred populations comprising between three and five individuals of each sex and of varying age (Bateman 1948). Based on his results, Bateman concluded that female reproductive success (number of offspring produced) is limited by the number of the egg cells (ova) they can create. On the other hand, he concluded that male reproductive success is only restricted by the number of available females. Male reproductive success, unlike that of the females, increases with the number of mates with which they attempt copulation. Bateman proposed that these differences in reproductive success stem from the dissimilar energetic investments in the production of gametes – the production of male sex cells (sperm) is much cheaper than that of females, resulting in a more expensive investment in reproduction within females. This results in a higher sexual selection pressure being placed on males, leading to a much larger observable reproductive variance. This is known as Bateman's principle.

Although Bateman's research remains among the most cited in the field, recent replication of his experiments revealed methodological and statistical flaws and deemed his results unreliable (Snyder and Gowaty 2007). Constrained by the knowledge and technology available in the 1940s, Bateman could not account for the fact that mutations that arise from inbreeding decrease the number of mates, as well as the viability of any subsequent generations or offspring. Bateman's additional fallacy was his sole reliance on the phenotypic features in determining parentage. By considering solely the offspring exhibiting the mutations of both parents, he disregarded all the instances in which only single parent's mutation, or no mutation at all, was displayed, thus skewing his sample and biasing his results.

### Robert Trivers and John Maynard Smith

One of the most influential evolutionary scientists, an American evolutionary biologist and sociobiologist Robert Ludlow Trivers, linked sexual selection and parental investment. He proposed that sexual selection is driven not only by the sexual differences in the production of sex cells but also in the sexual differences in parental investment, with the former promoting the latter (Trivers 1972). While not all species require parental care, the reproductive success of those that do is influenced by the different contributions of each sex. The higher-investing sex (typically females) are more selective against the opposite sex (typically males), the members of which will compete for the access to the higher-investing sex. It is worth noting that neither sex is passive: both will try to exploit the other – males by their promiscuity and females by confusing paternity, for instance, by evolving a concealed ovulation (hidden estrus).

The understanding of parental investment was further advanced in the 1970s by John Maynard Smith, a British evolutionary biologist. According to Maynard Smith, the majority of species require no parental care, while among those that do invest time and resources, it is possible to categorize species into those that provide either uniparental or biparental care. In nature, uniparental care appears to be the more prevalent of the two

systems. Furthermore, in species with internal fertilization, parental care is typically maternal, while species with external fertilization usually exhibit paternal or biparental care.

## Sexual Selection and Sexual Dimorphism

Sexual dimorphism is defined as being the morphological, physiological, or behavioral difference displayed between the sexes of a single species. The direction (i.e., which species is experiencing the selective pressure) and degree to which sexual dimorphism is expressed is indicative of differential parental investment. It is believed that the development of the secondary sexual characteristics is activated and governed by the sex hormones, expressed by testosterone, estrogen, and progesterone. In a scenario where the parental care is largely provided by the female, the variance observed in male reproductive success is expected to be large as the parent female will not be available for further reproduction during the nursing period. Theoretically this then leads to increased intrasexual competition between the males for those females that remain available.

In contrast, species that exhibit biparental care display a lower degree of variance within male reproductive success. In such species, the males that provide paternal care will therefore not be able to invest their energy in trying to secure additional mates. Such species are often sexually monomorphic, with members of both sexes being phenotypically similar, and comparable in both physical appearance and behavior. In species where males are the only sex that provide parental care, the variation of female reproductive fitness is typically high, with individual females often monopolizing access to one or more males. In such instances, males become the “selecting” sex, driving sexual dimorphism in the female population and initiating the evolution of secondary sexual characteristics. In nature, sexual dimorphism is manifested in countless forms and varies enormously in extent between individual species and even between subpopulations. The degree to which sexual dimorphism is expressed is

determined by the scale of the selective pressure and therefore also the ecological and demographic variables affecting the species or population. Furthermore, the resultant dimorphism may also be dependent on the extent to which the sex hormones influence development within a species.

## Sexual Dimorphism in Body Size

The most common form of sexual dimorphism is a difference in body size. If the males of a species are larger than the females, these differences are thought to have been driven by sexual selection. Whereas in the opposite scenario, where the females of a species are larger than the males, it is assumed that the selective pressure is connected to fertility.

Most primate species (including humans) display some form of sexual dimorphism in terms of body size, which is often most visible in skeletal dimension, canine tooth size, and musculature. Males of the Old World monkeys (Cercopithecidae), such as mandrills (*Mandrillus* sp.), baboons (*Papio* sp.), and proboscis monkeys (*Nasalis larvatus*), as well as apes, such as orangutans (*Pongo* sp.) and gorillas (*Gorilla* sp.), can, in some cases, be twice as large as the females in terms of body mass (Plavcan 2004). The opposite trend, however, is observed in some of the New World monkeys (Ceboidea), such as the Callitrichidae (marmosets and tamarins) and the typically monomorphic strepsirrhines – lemurs (Lemuroidea) and lorises (Lorisoidea) (Plavcan 2004). Male skeletal structures are frequently larger and show more intense cresting of bones (e.g., in *Gorilla* sp.), a reflection of the often increased muscle mass in the sex. Similarly, male gibbons (Hylobatidae) and howler monkeys (*Alouatta* sp.) exhibit enlarged and hollow hyoid bones, an adaptation that increases the resonance and range of their vocalizations. The observable differences in canine tooth size attributed to sexual selection are primarily found in the Old World monkeys and apes (catarrhines). In some species, male canines can be more than four times larger than that of the female (Plavcan and Ruff 2008), while the opposite has been observed in mouse lemurs (*Microcebus rufus*) (Thoren et al. 2006). Canine dimorphism is more often observed in the

maxillary canines (upper jaw), than in the mandibular canines (lower jaw), and it is believed to be a result of male intrasexual competition.

In invertebrates, body size dimorphism was found to be correlated with cannibalism in several families of spiders (Araneae) and praying mantises (Mantodea), although food availability and abundance also play an important role. In both groups, females are typically much larger than males. Males tend to show a preference for bigger females, who are not only more fertile but also less likely to eat them. In response to the females' cannibalistic tendencies, males of some wolf spider species (Lycosidae) have evolved anti-cannibalistic behavioral strategies, such as binding the females with silk or presenting the female with a "nuptial gift" (Wilder and Rypstra 2008). This behavior is a characteristic of many insect groups. In butterflies, many species that present "nuptial gifts" are polyandrous (females obtaining two or more males), and male/female ratio was found to increase with the degree of polyandry and gift size (Leimar et al. 1994). The majority of butterfly taxa show female-biased body size dimorphism.

The same pattern is essentially true for the majority of fish, with the general exception being that of species which exhibit intrasexual male combat or engage in male paternal care (Fairbairn 2013). For example, males of one species of cichlid (*Lamprologus callipterus*) in Lake Tanganyika can be as many as 60 times larger than the females (Ota et al. 2010). A further example of extreme sexual dimorphism can be found in the anglerfish (Lophiiformes), where small males exhibit sexual parasitism, becoming permanently attached and eventually absorbed into the much larger females, providing only sperm (Pietsch 2005).

### **Sexual Dimorphism in Color and Ornamentation: Sexual Dichromatism**

Sexual dichromatism is a form of sexual dimorphism where the males and females of a species display differences in color and ornamentation. This characteristic is highly prevalent among birds, amphibians, reptiles, and butterflies. An obvious example that illustrates sexual

dichromatism effectively is the different plumages observed between the two sexes of the Common Peafowl (*Pavo cristatus*). While the males' tails are long, ornamented, vibrant, and iridescently colored, female plumage is typically colored dull gray and brown. Such dramatic dimorphism indicates a strong sexual selective force manifested in the male birds, being driven by female mate selection. Importantly, to have reached such extreme proportions, the selective force present within the *Pavo* genus is likely to have been consistent in direction over a prolonged period of evolutionary time. In order for sexual selection to reach such intense dimensions, the selective force must be great, and the selective pressure must endure for a protracted period of time.

Sexually dichromatic features are considered honest signals – advertising information about an individual's fitness in an obvious and unmistakable manner. However, such conspicuous announcements carry many survival costs and can often increase an individual's visibility to predators or decrease their agility. The selective harvesting of African elephants for ivory provides a recent example, with individual bulls with the largest tusks being selectively targeted and killed for a larger economic reward. Such costly investment in sexually derived traits therefore often acts as a handicap for the individual animals. According to the handicap principle, proposed in 1975 by the Israeli biologist Amotz Zahavi, reliable signals that are highly conspicuous and undisguisable must always be costly to the individual. Such visible and often flamboyant characteristics indicate to their conspecifics that their fitness is so superior that they are able to afford to expend their resources in a way that individuals of lower quality would not be able to (Zahavi 1975).

Although lowering the individual bearer's survival probability, the long and elaborate tails of male peafowl carry worthwhile advantages, with males with more splendid tails being preferentially selected as mates. Significantly, male offspring will therefore be more likely to inherit the genes for a large and colorful tail, while any female offspring will be more likely to inherit a preference for selecting long and

colorful tails. Over a number of generations, this self-reinforcing coevolution will result in a Fisherian runaway scenario, where both the trait and the parallel preference for it become more prevalent. This is evident from the increasingly exaggerated characteristics observable in the sons and the increasingly choosier daughters in each subsequent generation. If female preference for an enhanced characteristic is strong enough to undermine natural selection, the trait will continue to exponentially increase even after becoming nonadaptive, until the costs of its expression become greater than the benefit it carries (Fisher 1999).

Sexual dichromatism is rarely found in mammals, with the exception of nonhuman primates. While most often of similar size, many species of Eulemur (Lemuroidea) show sexual dichromatism. In some species, for example, in the black lemur (*Eulemur macaco*), sexual dichromatism in pelage color is highly pronounced. Males are entirely black, while females vary from golden brown to chestnut brown, with white ear tufts. In other species, sexual differences are less discernible – for instance, the pelage of the collared brown lemur (*Eulemur collaris*) varies only slightly in color, but their heads and faces show distinct differences: females' faces are gray, while the male' faces are black and with more prominent reddish-brown cheeks (Mittermeier et al. 2010). Sexual dichromatism is particularly striking among black howler monkeys (*Alouatta pigra*), with males being completely black while females are golden brown. Similar dichromatism can be also observed in black-crested gibbons (*Nomascus concolor*): males are almost entirely black (apart from the white cheeks), while females are typically golden brown, with a black streak across their heads.

In order to accurately comprehend the implications of sexual dichromatism, it is important to consider the visual abilities of that particular species. For instance, over 90% of bird species previously considered monochromatic, showing no apparent disparity in gender coloration to the human eye, are now considered dichromatic to their conspecifics (Eaton 2005). Therefore, it is important that the full range of visual repertoire of

a species is taken into consideration before a species is declared mono- or dichromatic.

### Sexual Dimorphism in Behavior

Most sexually dimorphic behaviors are associated solely with reproduction and are believed to have evolved under sexual selection pressures. They can be divided into the following categories: courtship behavior, mating behavior, and parental care (Kelley 1988).

#### Courtship

Numerous vertebrate and invertebrate species engage in courtship displays, during which they can exhibit extravagant phenotypic features, and announce their desire to mate. Such behaviors include demonstrations of beauty and strength and are in some cases accompanied with ritualized movements (mating “dances”) and vocalizations. In the majority of species, courtship behaviors are performed by the male, with mate choice governed by the female.

Courtship has evolved under both intrasexual and intersexual selection pressures. Intersexual selection typically drives the dimorphism of courtship behaviors such as bird song or advertisement calls in frogs. Male songs are an indication of individual fitness, with the volume, duration, and complexity of the vocalization acting as a proxy to caller fitness. Many bird species are known to change or adapt their songs each season or even during the same mating season. Females of many well-studied species (birds, whales, and nonhuman primates) show a preference for more complex songs.

In conjunction with vocalization, many species employ elaborate movements or “dances.” One of the most prominent examples of this can be seen in the Australasian birds of paradise (Paradisaeidae). In one species, the Wahnes's parotia (*Parotia wahnesi*), in addition to their sexual dichromatism, males seemingly adapt their postures as to change their shape, by pushing their feathers to create a shape similar to ballerina's tutu skirt. This earned their mating “dance” the nickname “the ballerina dance.” Courtship behavior is, however, not reserved for birds alone. Male peacock spiders (*Maratus* sp.) engage

in courtship displays, which comprise raising of their iridescently colored upper abdomens and third pair of legs showing black white-tipped hairs, vibrating their peacock-like abdomens and opisthosomal flaps while moving from side to side, trying to attract females (Otto and Hill 2012).

In some species, males gather in aggregations in which they engage in competitive displays. This behavior is called lekking, and the aggregations of males are called leks. They are most prevalent in birds but can also be observed in insects, fish, amphibians, reptiles, and mammals. Females visit the leks and mate with males they choose but form no long-term bonds. Males of species with lek mating systems provide no parental care – the only resources they contribute are their genes. Although female selection is based on males' specific traits, this does not decrease species genetic diversity or lead to a runaway selection, as would be expected. This preservation of genetic variation is often referred to as the lek paradox. A possible explanation is the relatively limited amount of information males can signal during these displays. However, those signals are reliable, as they cannot be forged. According to the aforementioned handicap principle (Zahavi 1975), by selecting mates based on the quality of their secondary sexual characteristics (the state of which is reflective of individual's fitness), females increase the probability of their offspring also possessing desirably "fit" traits. In addition to physical attractiveness, sexually selected traits could signal individual's resistance to parasites (Hamilton and Zuk 1982). Parasites have often coevolved with their hosts and may influence or contribute to a population's genetic diversity. Rowe and Houle also recognized the relationship between sexually selected traits and general physical condition and proposed the theory of condition-dependent expression of male sexually selected traits. They argued that male traits are correlated with a number of genes that are involved in different aspects of physical condition, such as metabolism, nutrition, or muscular mass, and that the variation of these genes is maintained regardless of the sexual selection pressures from the female sex (Rowe and Houle 1996). Mutations and environmental effects can

further facilitate the preservation of genetic variance. According to the genic capture hypothesis, sexual selection operates on condition-dependent traits, and female selection therefore does not decrease genetic variance. Finally, it is possible that the male traits preferred by the females are not actually purposefully selected for but remain in the population due to their contribution to male overall attractiveness. This would mean that lek paradox does not really exist.

### Mating and Parental Care

The differentiation in mate acquisition by each sex is generally reflected in the species' mating system and is furthermore closely linked with parental care. In a monogamous mating system, an individual obtains and invests in a single partner. This system is often observed in species committed to biparental care and where males have relatively little chance of monopolizing more than one female. In some species, males form alliances, usually with kin, in order to maximize their reproductive success. Alliances also help to prevent other males from mating. The reproductive trade-off of these alliances is dependent on the extent to which mating is shared (as this often results in a single dominant male monopolizing the females) and the extent to which it increases individual fitness by increasing their foraging opportunities or decreasing the costs of defending a territory. This behavior is a characteristic of cetaceans (*Tursiops* sp.), lions (*Panthera leo*), and chimpanzees (*Pan troglodytes*).

In a polygamous mating system, individuals of one or both sexes obtain more than one mate during a breeding season. In polygynous systems, males mate with multiple females. The males of most polygynous species appear to have undergone a strong intersexual selection of the female-preferred traits or intrasexual selection of traits associated with male-male competition. This mating system is prevalent in species where males do not provide parental care, allowing them to monopolize more than one female. In polyandrous systems, females mate with multiple males. This rarely encountered type of mating system is characterized by a role reversal in courtship and parental care and where females compete

for males and or territories in order to attract males.

Differences in parental care are considered to be a reflection of the (previously discussed) sexual differences in the investment into the production of sex cells. Paternal care is believed to have evolved to compensate for the higher reproductive investment of the female sex. Biparental care generally results in a beneficial outcome for offspring in terms of survival, by improving the protection against predators and environmental extremes, as well as by additional food provision, and in some species the direct transfer of skills. Biparental care is observable in most bird species, with paternal contribution correlated with the equality of investment in egg incubation and food provision. Biparental care is also present in some families of amphibians and fish. Uniparental maternal care is the most common type of parental investment among the mammalian species, especially rodents, canids, and primates. An opposite case of a uniparental paternal care is typical in seahorses (*Hippocampus* sp.).

### Context-Dependent Sexual Dimorphism

It is also important to note that while some species exhibit ontogenetic sexual dimorphism – a permanent difference between males and females – others show a dynamic pattern, with sexual differences occurring only seasonally, for example, during the breeding season. Dynamic dichromatism often functions as a visual sexual indicator, particularly in species which form large breeding aggregations (e.g., frogs). In some species (e.g., the yellow toad, *Incilius luetkenii*), the dynamic dichromatism only lasts for a couple of hours (Doucet and Mennill 2010). These color differences range from subtle alteration of shade to differences in both color and pattern. The male moor frog (*Rana arvalis*), for example, is typically a reddish-brown but turns blue during the mating season. Similarly, the Malagasy frog *Boophis madagascariensis* undergoes a brief transformation to a bold yellow coloration for a short period during their explosive breeding bouts (pers. comm. Hyde Roberts, Nov 2017). Such dynamic dichromatism is also a common characteristic in many birds. For example, male red fody

(*Foudia madagascariensis*) produces a bright red plumage during the austral summer when breeding occurs. Such dramatic and dynamic sexually driven dimorphism is not restricted to dichromatism and can also occur in body size. For example, male squirrel monkeys (*Saimiri sciureus*) show an increase in body mass of up to 25% during a 2-month breeding season. This phenomenon is known as “male fattening,” particularly affecting their upper torso, shoulders, and arms, and is a product of both intra- and intersexual selection (Stone 2014).

The expression of sexual dimorphism and its elaborateness can vary within the mating season as well, depending on the context of its expression. For instance, vocalizations of big brown bat (*Eptesicus fuscus*) males are only dimorphic in a reproductive context but remain monomorphic in other social contexts (Grilliot et al. 2009).

### Sexual Conflict (Sexual Antagonistic Coevolution)

When the sexual morphology of one gender changes over time in order to counteract that of the opposite sex so as to maximize reproductive success, it is considered sexual antagonistic coevolution or sexual conflict. Numerous examples can be found in the evolution of reproductive organs. Male mating behavior of numerous insect species is detrimental to female fitness. A variety of invertebrate taxa, including fruit flies (*Drosophila* sp.) and bed bugs (*Cimex lectularius*), reproduce by means of traumatic (hypodermic) insemination. This mating practice involves the male piercing the female’s abdomen with his penis and injecting his sperm through the wound into her abdominal cavity (Siva-Jothy and Stutt 2003), despite the female having a genital tract. Males try to inseminate as many females as possible, but the more times a female is inseminated, the less likely she will be to survive, due to repeated punctures of her abdomen. In order to avoid multiple matings, females have adapted their morphology by evolving paragenital systems, such as spermathecae, which mitigate the effects of traumatic insemination. Some species

possess a spermatheca, an organ they use for receiving and storing sperm; other species have evolved a pseudospermatheca, which performs the same function. These organs allow the females to choose which sperm fertilizes their eggs. Some species (e.g., *Drosophila melanogaster*) can expel the sperm they do not need, with the males not knowing whose sperm will be dispelled.

Males of polyandrous species have evolved under the evolutionary pressure of sperm competition – a competitive process between the spermatozoa of multiple males attempting to fertilize the same egg. As a result, they have evolved adaptations that increase their reproductive success. These adaptations often include modifications of their (comparatively fast-evolving) genitalia. Some species, such as seed beetles (Chrysomelidae), have evolved spiny penises, which help them hold onto a female and enable them to quickly reach the female's reproductive tract. The females suffer injuries, which increase with the number of matings. Each mating therefore decreases the likelihood of her subsequently mating with additional males. In response, females have evolved thicker walls of their reproductive tracts and increased their immune capacity (Rönn et al. 2007). Males of various species of birds, reptiles, and mammals have developed keratinized penile spines. In Eastern red bats (*Lasiurus borealis*), the penile spines face backward, which facilitates the insertion and impedes the extraction either involuntarily or voluntarily. This is thought to facilitate sperm injection while also allowing the male and the female to stay together during the midair copulation, referred to as the in-flight locking hypothesis. Another example of male coevolution can be found in the number and motility of spermatozoa. As they are costly to produce, selection generally favors larger numbers of small, but fast, sperm cells.

In addition to the morphology of the reproductive organs and sex cells, examples of male coevolution can also be found in adult behavior. Such behaviors can be directed toward either defensive or offensive adaptations. Many species of insects, birds, lizards, and mammals have evolved a defensive behavior called mate guarding. This behavior, in which male individuals engage in

either before or after copulation, involves their attempted prevention of any other males approaching and mating with the female. Some species only practice strategic mate guarding during female's fertile period. This is particularly efficient for the males, as it allows both within-pair and extra-pair paternities. It is also beneficial for the females, as they can benefit from the physical protection from predation and harassment from other males. Sperm partitioning (males conserving their sperm supply by reducing the quantity of sperm ejected) or prolonged copulations (which increases the amount of sperm deposited in female's reproductive tract while also preventing the female from copulating with other males) is another example of a behavior associated with male coevolution.

Unlike the defensive adaptations, which decrease future sperm displacement, offensive sexual adaptations often act with the intention of displacing the previous male's sperm or limiting the other male's opportunities to reproduce. The presence of armaments facilitates offensive behaviors, and their display is often enough to deter intrasex competition. Phenotypical examples include antlers of deer (Cervidae) or stag beetles (Lucanidae), while behavioral examples include males of *Drosophila* sp. releasing seminal fluids containing toxins and pheromones that destroy the sperm of their rival predecessors. The results of sperm competition, however, often depend on female sperm choice (Birkhead 1998). A form of cryptic female choice includes non-random biases resulting from female morphology, physiology, or postcopulatory behavior. Examples include a reduction in the rate of offspring produced through a decline in egg maturation and pregnancy block (a tendency of females, mostly a characteristic of rodents to abort their pregnancies if exposed to the scent of unfamiliar males) or a decreased investment into offspring.

## Summary

Sexual selection is a special type of natural selection that was first proposed by Charles Darwin. There are two recognized mechanisms of sexual

selection: intrasexual selection (members of the same sex competing for access to the members of the opposite sex) and intersexual selection (members of one sex choosing their mates among the members of the opposite sex). Depending on the differential investments in reproduction – from the production of sex cells to parental investment – sexual selection pressures can differ greatly between the male and the female sexes. Strong sexual selection pressures result in sexually dimorphic traits, which can be manifested in either physical appearance or behavior. Both sexes seek to optimize their reproductive success; often this leads to conflict between the sexes. This evolutionary arms race has driven the evolution of sexually reproducing species.

## Shame and Guilt

Jennifer Vonk

Department of Psychology, Oakland University,  
Rochester, MI, USA

### Synonyms

[Compunction](#); [Contrition](#); [Culpability](#); [Humiliation](#); [Remorse](#); [Repentance](#); [Self-reproach](#)

### Definition

Shame is a feeling of reproach directed at oneself for having committed a behavior that evokes anger and/or disgust in others. Guilt is a feeling of remorse for having caused pain or other negative feelings in another.

### Introduction

Shame and guilt are considered secondary emotions along with embarrassment, jealousy, envy, and pride (Miller & Leary, 1992). Except for jealousy and envy, secondary emotions involve an evaluative component that involves reflection on how one is perceived by others (Morris et al., 2008). For example, embarrassment stems from the feeling that one has done something to encourage derision from others. Shame stems from the feeling that others are disgusted or angered by something one has done or a failure to live up to expectations. Guilt follows some transgression against moral rules pertaining to the treatment of others and the resulting negative consequences such as pain or distress for others (Keltner & Buswell, 1997). It can therefore be speculated that the experience of secondary emotions depends upon some level of theory of mind, or the attribution of emotions to others (Tangney, 1992). In support of this supposition, children with autism that experience theory of mind deficits differ from neurotypical children in their responses to narratives concerning

embarrassment, but not narratives concerning sadness or happiness (Capps et al., 1992). Theory of mind might also be necessary for experiencing vicarious emotions, such as being embarrassed on behalf of another individual. The secondary emotions likely emerge along with self-awareness and its markers, such as mirror self-recognition and the use of personal pronouns, around the age of 18 months in neurotypical human children (Lewis et al., 1989). Because there is arguably no strong evidence for self-awareness or theory of mind in nonhumans, it might be doubted that animals experience secondary emotions, such as shame and guilt (but see Bekoff, 2002).

### Adaptive Value

Secondary emotions may function to maintain social cohesion in that they provide an internalization of communal norms and rules and promote peaceful coexistence by preventing actions that cause negative emotional experiences for others (Miller & Leary, 1992). Thus, it might be expected that self-conscious emotions, such as shame and guilt, have evolved in species that live in large, complex social groups. These emotions would serve little adaptive purpose unless directing one to maintain and repair long-term social bonds in order to accrue benefits such as group protection and reproductive opportunities. Keltner and Buswell (1997) review the work on appeasement in animals, which has been suggested as an analog to embarrassment (de Waal 1986; Leary et al., 1992). They describe common features for appeasement displays across species, such as gaze aversion, downward head movements revealing the neck – resulting in an apparent size reduction, and self-touching or grooming. Such behaviors serve to reduce aggression or retaliation after a social transgression, and thus function to promote group stability and restore social functioning (Miller & Leary, 1992). The experience of self-conscious emotions may be linked to evolutionary precursors for morality, although even chimpanzees appear primarily concerned with fairness with regard to their own treatment

rather than with the fair treatment of others (Price & Brosnan, 2012).

### Research

Given the assumed dependence on other cognitive traits such as self-awareness, theory of mind, and morality, and the lack of strong evidence for these traits in nonhuman animals, it is perhaps unsurprising that there is little empirical research investigating the presence of self-conscious emotions in nonhumans. Furthermore, it is challenging to test the presence of subjective feelings in nonverbal species. For that reason, researchers must rely on observations of behaviors that have been linked to human experiences of shame and guilt in contexts where these emotions would be evoked.

Dog owners report that dogs behave as if they feel shame when they have misbehaved even before the owner encounters the evidence (Hecht et al., 2012). Horowitz (2009) experimentally demonstrated that dogs behaved as if they felt guilt or shame specifically after committing a forbidden act. Dogs either ate a food item that was forbidden or the food item was removed by experimenters out of sight of the owner. Dogs then exhibited “guilty looks” when the owner returned but the behavior could also be interpreted as anticipation of punishment following specific behaviors based on past experiences. This alternative interpretation is bolstered by the finding that dogs were more likely to display the behavior ascribed to feelings of guilt in the presence of a human that scolded them compared to one that was friendly. Furthermore, dogs that had not actually consumed the food looked guiltier than dogs for whom the experimenter had removed the food, lending credibility to the idea that dogs were fearful of retaliation rather than guilty (Horowitz, 2009). Dogs in the Hecht et al. (2012) study had also been scolded for eating the food in a baseline trial before the owners judged which dogs had eaten the forbidden food. This baseline trial also gave the owners information about how the dog behaved in similar situations (Ostojić et al., 2015). Ostojić et al. manipulated the dogs’ own

action (on which guilt should be based) as well as the evidence of their misdeed. Following Horowitz (2009), the dogs ate the food or the food was removed by the experimenter, but in both conditions, the food was either absent or replaced by the experimenter and owners were instructed to behave in a neutral rather than a scolding manner. As in Hecht et al. (2012), owners recorded whether they thought their dogs had eaten the forbidden food. In this study, owners did not report differences in dogs' guilty look across the conditions suggesting that guilt-like behaviors were not influenced by either the dogs' own behaviors or the evidence of their misdeeds (whether real or experimentally manipulated). Ostojić et al. concluded that the dogs' guilty behaviors were triggered by the owners' scolding behaviors in the previous studies, rather than by an internalized subjective experience of guilty feeling. However, they acknowledge that future studies should remove the possibility that experimenters inadvertently communicated that it was permissible to eat the food.

Researchers have asked animal caregivers to report frequencies of observed expressions of emotions in their animal companions, and the contexts in which these expressions of emotion occurred (Morris et al., 2008). Morris and colleagues found that owners reported embarrassment and shame at very low frequencies. Secondary emotions in general were most commonly attributed to dogs rather than other animals. Even with the concern that the survey report method is especially vulnerable to anthropomorphism, the low reports of secondary emotions cast further doubt that these emotions are experienced in animals as they are in humans.

## Shaping

Cinzia Chiandetti

Department of Life Sciences, University of Trieste, Trieste, Italy

## Synonyms

Chaining; Differentiation of a response; Modeling; Successive approximations

## Definition

Shaping is a technique of training used to make an animal emit a desired complex behavior through the reinforcement of segments of such behavior.

## Introduction

Within the framework of the experimental analysis of behavior, Skinner's approach was based on empirical observations of behavior, which could be measured, predicted, and controlled. By means of this surgical analysis, each segment of a complex behavior could be extrapolated and studied and hence reinforced whenever necessary. The method used to mould a response followed the operant conditioning principles, according to which the behavior is sensitive to its consequences.

While there are responses that could be spontaneously emitted by an animal (like when a hungry rat touches a lever by randomly moving in the training chamber) and that can be readily reinforced, other more complex desired behavior may not be spontaneously emitted by the animal (like for instance, if we wanted the rat to press the lever after having make a 360-degree turn on the left). In other words, the display of an elaborate

behavior may be unlikely to appear in its complete form or may not belong to the individual's repertoire (e.g., lifting a marble up with the forepaws and insert it in a tube), and therefore it will never occur spontaneously to be reinforced. In such cases, the final desired behavior can be reached by reinforcing some of the animal's spontaneous responses, at the beginning only vaguely resembling the target behavior, and then by progressively reinforcing a more complex pattern of responses that more closely approximate the final desired behavior. Specifically, small segments of the final behavior can be defined, and once a given step has been conditioned, the reinforcement is shifted to the next step and made contingent upon the following segment of behavior, until the final desired behavior is reached. By means of this shaping technique, a rare or unlikely response with a specific topography reaches a high probability to be emitted in virtue of a continual process of differential reinforcement that constructs a complex and coherent behavior out from single small variations.

Skinner (1937, p. 277) provided an instance of shaping of a rat's press-lever response. By dissecting the target behavior (i.e., lever pressing) in subsequent steps, he hypothesized the necessary separate responses in a chain that needed to be reinforced in order to obtain the final response:

1. Approach to the site of the lever
2. Lifting the nose into the air toward the lever
3. Lifting the fore-part of the body into the air
4. Touching the lever with the feet
5. Pressing the lever downward

In Skinner's view, almost all animal behavior (including human language acquisition) could be learned through this program of successive approximations (Skinner 1951), to the point that we are all gently shaped by our environment that models our habits and preferences: in a word, our culture (Skinner 1971). He masterly demonstrated this idea by training one specific lab rat, Pliny, to perform a series of behaviors none of which belonged to Pliny's repertoire. Pliny became able to pull a string to get a marble from a rack, take the marble with the forepaws, and drop it from the top of a tube (Skinner 1938, p. 340) in a fluid sequence.

## The Story of Shaping: Its Antecedents and Its Discovery

Although the use of shaping as a procedure to model complex behaviors was posited by Skinner in 1938, there is at least one antecedent use. Konrad Most, Colonel at the Royal Prussian Police Headquarters, was a pioneer in training service dogs. He synthesized the principles he adopted during training in the book *Training Dogs* (Most 1910/1954). Well before Skinner, at least 28 years earlier, Most described a procedure that parallels the shaping technique. Indeed, he claimed that the “slightest progress toward the desired behavior should be reinforced, not only with terms like ‘good boy,’ but with fondling” (p. 34) thus anticipating Skinner’s description and use of shaping.

It is also worth noticing that, when Skinner wrote about Pliny’s performance, he was probably not entirely aware of the relevance of shaping. At that time, the word “shaping” was not yet in use to indicate the training method; moreover, all behaviors shaped in lab rats before 1943 were obtained through an approach in which the experimenter was a passive observer while mechanical and electrical programmed chambers delivered reinforcers with specific contingencies. It was the physical environment that was shaping the animal’s responses.

One serendipitous event became the hallmark for shaping in Skinner’s mind, as reconstructed by Peterson (2004). Skinner was atop a flour mill with his students Keller Breland and Norman Guttman, training pigeons to guide bombs for a project related to war (Skinner 1960). In that occasion, as reported in the paper appeared in *American Psychologist* in 1958, Skinner started training the animal by hand to swipe a wooden ball; he decided to watch the animal’s responses and administer himself the reinforcers by hand, following certain approximations of behaviors. The pigeon soon started doing exactly what Skinner had in his mind (i.e., touching the ball with the beak and moving the head with a certain inclination to hit it). Skinner discovered in that exact moment how fast the process of learning could be; hence he recognized the significance of an animate social reinforcer to model a complex

behavior. After this sort of insight, he coined the term “shaping” that he introduced for the first time in 1951 and systematically used in all subsequent works, replacing concepts such as successive approximations or differentiation of a response that were used before, and exploiting the heterogeneous applications of shaping.

## The Practice of Shaping (and What It Is Not)

Keller and Marian Breland, after studying under Skinner’s supervision the operant principles to train rats and pigeons, decided to abandon the academic career to work in the field of advertising and entertainment. They developed a broad application of the behavior analysis shaping animals’ behavior for commercials, parks, and their “IQ zoo”, where animals attracted tourists with their apparent human-like behaviors (Breland and Breland 1951). The Brelands trained several different species to display very complex behaviors (as for instance, pigs to eat breakfast at a table or run the vacuum cleaner, ducks to play the piano, hamsters to trapeze-swing, and so forth) getting popular media attention for their work (Bailey and Gillaspay 2005). Although a great initial success, they soon discovered a phenomenon that they termed “instinctive drift”; after having been conditioned to a specific learned response, each animal gradually changed it drifting towards instinctual behaviors related to natural and species-specific responses to get food; such drift arose in spite of delay or preclusion of reinforcements (Breland and Breland 1961). The Brelands (1961, p. 682) provided several examples of such phenomenon and mentioned, for instance, the conditioning of “a raccoon putting money in a piggy bank” that become impossible because “the rubbing behavior became worse and worse as time went on, in spite of nonreinforcement.”

Nevertheless, the operant method to shape animals’ behavior within the context of species-specific responses was effective and was extended to marine mammals for the first time with the Brelands, who also wrote a manual to train dolphins (Breland 1955), which is still influential

even on contemporary dog-training (Pryor 2005). Indeed, one relevant aspect is that Skinner shaped responses that were part of the animal species' repertoire. For instance, in the famous video in which he trains pigeons to play ping pong, the birds are reinforced to use their natural pecking behavior against the ball to prevent it from falling down on their side; the pigeons are never reinforced to use their wings or feet to hit the ball.

In contemporary practice, trainers know that the shaping method does not proceed in a positive linear fashion; rather it includes steps that are verified and modified frequently during training so that, if a certain response needs to be fixed, previous segments of the target behavior can be reinforced again. Whenever a new approximation of behavior does not appear, it is necessary to reinforce the previous one again; if no improvement is reached and no new approximation occurs, the trainer has to reinforce again a previous complete behavior again. Hence, the trainer is actively involved in judging and reinforcing the animal's responses that cannot be easily shaped by automatic contingencies.

Trainers often use the clicker, a mechanical device emitting a distinct 'click-clack' when pushed and released, to mark the specific segment of behavior that will result in food reward (Pryor 2005). The clicker anticipates the reward acting as a secondary reinforcer in virtue of classical conditioning. Its practical advantage is that of reducing the use of food during shaping (the treat is instead provided only occasionally to avoid extinction). Note that, in principle, this holds true whatever the nature of the secondary reinforcer (Chiandetti et al. 2016) and hence the clicker should be preferred depending on other factors (i.e., dog's temperament or breed, trainer's expertise, environmental setting, possibility to timely deliver the primary reinforcer, etc.).

A novel behavior, especially in companion animals, can be elicited using other strategies that are confused with shaping by nonexperts only because food rewards are implemented to reinforce a behavior (Kaplan et al. 2002). One strategy, for instance, is modelling: the animal is coaxed to perform a behavior and then reinforced. Another strategy is luring: the animal is guided by a treat and has to follow it to

display the pattern of behaviors before getting it as a reward. These forms of learning are not shaping since the animal is not emitting spontaneous responses; rather, the animal is forced or guided by the trainer to display directly the final behavior, with no intermediate steps to the target behavior. A further method is capturing; it is waited until the animal spontaneously manifests the desired behavior, which is then rewarded. The unpredictable time necessary to observe the final target behavior by chance is exactly what is possible to avoid through shaping, as Skinner originally understood.

## Definition

It is the restricted ability for retaining a limited amount of information for active usage in the brain for a brief duration.

## Introduction

Memory is the special ability to store and retain any stimulus for future usage. It can be explicitly divided into two types depending of the duration of the stimulus: short-term (STM) and long-term memory (LTM). There are many further types of memories to be classified under these broad categories. External stimuli are stored in the form of memory by the neural circuit of the neocortex in the brain. Various models have been proposed to define the working of STM and LTM. The modal model of Atkinson and Shiffrin states that short-term memory storehouse can transfer the STM to LTM if kept for a long duration. On the other hand, the contradiction by the research of Tulving and Pearlstone denies this connection (Eduardo and Francisco 2017).

Thalamic neuronal projections serve the direct purpose of transmitting sensory information to cortical neuron circuits as suggested in various studies (e.g., Dubreuil 2019). Processing of stimuli is carried out by a larger number of neurons. Various neural model architectures are proposed to be made of cortical columns. The hippocampus is also associated with information storage in terms of STM and LTM (Bird and Burgess 2008). An initial step is performed by glutamate receptors beginning with the activation of AMPA and NMDA. NMDA plays its role in the learning exercise of memory, and AMPA serves the role in formation of memory (Izquierdo and Medina 1997). Following the cascade of events in the hippocampus, other regions like the amygdala and extrahippocampal parts are involved in memory consolidation (Izquierdo and Medina 1997).

There are two kinds of STM mechanisms identified: the recurrent connectivity where specific stimulus patterns are rebounded by specific neural activity manners and the feed forward connectivity model, which represents stimulus in pattern of delay lines. The neural architects are in serial or

parallel manner; most studied is the trees of recurrent networks (TRN) neural architect model. It has capacity limits, which serves as limitation for the model; i.e., it can depict limited sensory output representation (Dubreuil 2019).

## Neural Aspects of the Short-Term Memory

Memory is expressed either as the primary memory, i.e., short-term memory, or the long-term memory, i.e., secondary memory. Memory is stored and distributed in the form of neural circuits in the brain. The STM captures the external world depictions; i.e., audio verbal or visual aspects of stimulus and stores it in the form of neural signals patterns, which are then reproduced from the storehouse. LTM and working memory (WM) are built upon the operations of STM systems. Being fundamentally the function of cognition, it is suggested that STM activity increases with age until adulthood.

Depending upon the visual span on a stimulus, STM is created. Memory storage involves the frontal cortex functioning. It is understood that STM can be considered as the type of memory involved only when the neurons firing and cell assembly is active throughout the process. Short-term memory generated undergoes the biological pathway of post-translational modifications and can generate rezoning from pre-existing networks. Memory was understood by Craik and Lockhart as a function of storehouse (Camina and Francisco 2017). Short-term memory has further components; i.e., visual short-term memory (VSTM), verbal short-term memory (vSTM), and audio verbal short-term memory (AVSTM). VSTM has been maintained throughout various species. The visual component of STM plays a prominent role in integration of all visual aspects and its depiction (Gibson et al. 2011).

## Development of STM Capacities Across Species

Humans have evolved a cognitive and conscious memory system. Nonhuman animals may not

have the exact same abilities but show quick recognition of items. The memory span of chimpanzees has been found to be around five items. Other apes show the working memory capacity of four to five items. Similarly, non-primates have shown a memory span for four items, whereas humans have developed a memory span of seven items maximum. Humans have evolved effective retrieval systems (Manoochehri 2021). Comparative studies have shown that monkeys have lower storage capacities than humans.

Animals such as dolphins, rats, and macaques have been observed for their episodic memory and buffer system. Apes like chimpanzees are known to remember their own behavior of a short period. Chimpanzees have been seen to have the skills to create long-term memories. Additionally, they also display the retrieval mechanisms of memory (Tomonaga and Kaneko 2014).

For humans, there is a prominent role of visual STM for behavioral actions. Comparative work with pigeons has assessed comparable capacities. Although the development of storage capacities is highest in humans, similar behaviors are observed in terms of visual STM in both species. In fact, pigeons have shown evolution of a superior visual system. The neocortex layers are absent in pigeons so the representation techniques are quite simpler in them (Gibson et al. 2011).

## Types of Memory

Memory can be divided on the basis of duration (STM, LTM) and behavioral demonstration into distinct types. According to memory systems, there are two divisions, declarative (explicit) and procedural (implicit) memory. Declarative memory consists of facts and events that can be consciously retrieved and depend upon hippocampal areas. Procedural memory, in contrast, consists of skill learning, i.e., the skills we develop with practice carried in the cerebellum (Vianna et al. 2000). Apart from this, episodic memory is the memory where an individual has the memory of personally experienced events.

Working memory (WM) is defined as a stage for alteration and storage of data temporarily for

cognitive tasks. It is the memory we use to perform strategic behavior. The working memory model of Baddeley and Hitch's model suggests the buffers, visuospatial sketchpad, as a component of working memory. The main functions of this sketchpad are to form a visual spatial representation of the visual world through the eye movements. Apart from the debate over the well-defined meaning of WM, it is said to include short-term memory mechanism to carry its use accordingly, along with the attention-based aspect of WM (Cowan 2001).

In contrast, LTM is the consolidated memory that stores data of prior events permanently for a long duration. To form a long-term memory, the data has to follow a cascade of events in the hippocampal regions, particularly CA1. It takes about a maximum of 6 h to undergo the events. It has been said undoubtedly, STM is kept in LTM to undergo consolidation. STM can be preserved but no experiment has proved the same for LTM (Izquierdo and Medina 1997).

## Distinction of LTM and STM

The distinction between STM and LTM has been validated by various experiments showing important dissociations. For example, the effects of certain drugs on both are different; deficits in the LTM and STM storage and retrieval mechanisms in people with some brain injuries or lesions have also been seen to be different. Specific brain lobe damages show its associated memory impairments keeping the other memory system intact. Temporal and parietal lobe defects show STM impairments, whereas medial temporal lobe lesions show effects on LTM, keeping the STM conserved. The multistore model also represents distinctions between STM and LTM and gives separate buffer theory for LTM; hence, storage processes in LTM are separate from STM (Jonides et al. 2008). As stated earlier, apart from the experimental segregation, STM and LTM are different in duration of memory storage. The decay limits and the interference pattern are the characteristic feature of STM. Also, the capacity of STM differs from LTM (Jonides et al. 2008).

## Interactions Between LTM and STM

LTM and STM share similar neural retrieval (recall) processes. The frontal lobe plays this role in both (Jonides et al. 2008). Many imaging techniques and experiments have shown similar activities in brain regions during memory retrieval in LTM and STM. The chunk capacities of memory also somewhat establish the dependence theory between LTM and STM. It is claimed that chunks are a characteristic of LTM which helps in STM retrieval processes. Interaction in terms of neural aspects and functional aspects are studied.

Unitary model concludes that there are no separate systems for STM and LTM. Both types of memory share common temporary activation representation. These activations are studied in frontal, neocortex, and pre-frontal cortex areas.

## Activation and Retrieval Process (Mechanism)

The memory is activated when a familiar information is present, and it remains active for a particular duration of time. This familiar data can be present in the LTM for a permanent time period. The external stimuli make it easy for an individual to recall a significant data. This implies that LTM helps in retrieval process of STM. According to meta-analysis studies, prefrontal cortex regions both anterior and lateral are involved in retrieval of memory. The activation process is quite similar in both LTM and STM as seen by neuroimaging techniques (fMRI) for the prefrontal cortex. The site of activation for LTM retrieval matches with activations seen with STM retrieval stages (Jonides et al. 2008).

A rehearsal process is proposed to be an efficient retrieval mechanism and maintenance technique for WM, LTM, and STM. The effectiveness has been seen with computational modeling of WM (Oberauer 2019). Evidently, for the retrieval process, immediate response from chunks is focused at attention. Be it LTM or STM, to recall any memory, capacity limit serves as a function of attention (Cowan 2001).

## Development of STM

As studies suggest, memory formation takes place in the hippocampal regions with some processes taking place in amygdala and entorhinal cortex followed by retrieval mechanisms. Both the glutamate receptors, AMPA receptors activation, and triggering of NMDA receptors are known to initiate the process of memory formation. Some messengers like nitric oxide and carbon monoxide take up the regulation of glutamate secretory levels (Izquierdo and Medina 1997).

Short-term memory formation follows three main steps for production. The steps involve encoding, maintenance, and retrieval pathways. In the encoding process, the individual takes up the data from external world in the form of perceptions and stored data from the past. The focusing of events plays a role in cognitive storage, which is controlled by past events or capacity basis. These physical world representations are converted into cognitive focus. Maintenance is the process of preventing the stored information from decaying or forgetting mechanisms which can be caused due to any interference stimulus. Although no particular model is suggested for this activity of the brain, hypothesis of rehearsal has been indicated for maintaining the encodings. The process also includes refreshing, elaborative rehearsal and articulatory rehearsal techniques (Oberauer 2019). The brain cortex regions play a part in retrieval mechanism for both STM and LTM (Jonides et al. 2008).

Many experimental studies show the formulation of memory can take place through various mechanisms. These include language sample and modeling and computational modeling setup, which are assumed to enhance linguistic activity and associative learning in children (Jonides et al. 2008).

## Memory Storage Capacity

The term chunk is used to define the capacity of STM. It was defined as collection of thoughts and concepts in brain. It is independent of size or words or time span of words used and the already

existing chunks. Chunk is taken as the fundamental unit for stored data in STM (Norris et al. 2020), although this representation of chunk's patterns hasn't been confirmed by any model.

Chunking is a cognitive process to inhabit more data in a compressed form in the STM. On the contrary, an alternate theory describes that chunks are represented in LTM but not in STM. This suggests that these chunks in LTM reconstruct the data when they come in contact with familiar items in STM (Norris et al. 2020).

STM is evidently reported as a verbal system, which includes phonological store and basic speech units. The capacity can be influenced from word span and its duration of span. Word length and phonemes set a limit in capacity for STM. Also, reading rate is directly proportional to memory span. Fast readers are able to store more correct data. Experiments to interpret the relation of memory span with memory capacity were done parallel to the decay theory implications (Baddeley 2000).

The storage capacity has several limits instead of a single limit (Cowan 2008). It is also estimated to have four chunk limits, but evidence has suggested seven chunk limits. These capacity limits are also specific in nature to the sort of information being processed. Object complexity and familiarity determine the capacity limits.

## Storage Buffers

Storage buffers are the identities holding the copy of data in the memory. The stores are distinctive for LTM and STM. Memory storehouse can be of two possible ways, long-term storage and temporary storage, which is kept as buffer storage. Buffers store the items in coordinated patterns occurring in visual pattern. According to modal model, three kinds of memory stores are identified; perceptual buffers, short-term store, and long-term store. Based on empirical findings, a fourth buffer called episodic buffer is proposed (Baddeley and Hitch 2019).

STM is observed to depend on a phonological code, whereas LTM is dependent on semantic factors. The initial model of WM sketches three

components of the limited capacity system: central executive, visuospatial sketchpad, and a phonological loop. The phonological loop model describes the working of a storage buffer to illustrate an efficient way to combine forms of input. This idea for phonological storage in STM is proposed by Baddeley's work. It keeps the speech and visual data for short duration, which is maintained by rehearsal methods. Cowan's model describes more about rehearsal methods conducting the recoding of data, whereas the episodic buffer keeps the temporary event data (Norris 2017).

## Mechanism of Decaying/Forgetting of STM

Decaying or forgetting of events stored in our STM can be broadly due to two reasons, i.e., decaying due to time span or interference from the external world. One of the factors for decaying can be decreased activation mechanism for STM and no synchronization in the firing of neurons. Either of these reasons can be a contributing factor for forgetting of STM. Neural evidences observed are the decline of activations in the posterior sector of frontal cortex.

According to interference-based decay theory, new memory or new data can suppress the older memories with time. Also, lower retention intervals and retrieval mechanisms also play a role in the process of decay. Hence, overlapping of memory occurs in the interference theory (Jonides et al. 2008). However, exact models or experiments to prove time-based decay theory have not been reported yet.

## Training Methods for STM

The training of STM is significantly based on the ability to retain more and better retrieval mechanisms. Recalling of events in retention intervals helps to keep the memory intact. Some methods have been experimented to increase the memory span for verbal STM. The first method is visual digit span method, where digits are played in front

of the participant at a fixed interval of time and the participant has to retrieve the sequence of the digits on the computer manually. This test assessed the visual training of STM.

The second method is spoken digit span, which involves a speaker who recites the numbers with fixed intervals and the participants recall the numbers spoken. Similarly, letter span, pattern span, and direction change methods are also conducted. With the stated training techniques, improvement in performance was observed gradually. But these training methods are of no effect to increase the capacities of STM (Norris et al. 2019).

## Conclusion

Memory formation takes place in the cortical regions involving the hippocampus. STM is the immediate memory of event in our cortex. A lot of theories have been proposed to define neural architectures of STM and LTM. The multistore and unitary model theories depict contradictions to one another in terms of relation between STM and LTM. Apart from the models and structures, capacity limit is the fundamental area for research. Humans have limits for storage capacities in STM, yet their significance is to be answered. What is the definite chunk capacity limit of STM and how it can be enhanced by any intervening methods are the questions still to be answered.

## Siblicide

Andrew Goldklank Fulmer  
Lehman College, City University of New York,  
Bronx, NY, USA

### Definition

Siblicide is an event in which one or more individuals kill another individual born to their same parent(s).

### Explanation of Behavior

Siblicidal behavior involves the killing of an individual born to the same parent or parents as their killer. It is taxonomically widespread (Mock et al. 1990; Salmon and Hehman 2014) and may evolve either as a facultative or a fixed “obligate” behavior (e.g., Anderson 1990). In obligately siblicidal species, members of a species universally kill any available siblings. This behavior by itself seems likely to reduce the fitness of both parents and siblicidal individuals. Parents stand to lose direct fitness, and siblicidal individuals stand to lose indirect fitness. Hamilton’s rule predicts that siblicide is inherently disadvantageous unless some benefit (for example, food monopolization under scarce resource conditions) outweighs the loss of the related individuals (Dobler and Kölliker 2010; Leippert et al. 2000). Given that siblicide occurs with such a range of frequency across such a range of taxa, several explanations for its evolutionary value have been put forward.

It is worth noting that these are not mutually exclusive.

When resources fluctuate, it may benefit the fitness of the parents to produce more offspring than can survive. Under such conditions, siblicide may be advantageous for both parents and offspring. For parents, siblicidal offspring may be a way to reduce the number of mouths to feed – a literally morbid version of the “helpers at the nest” concept. Siblicidal individuals, in turn, increase their share of parental resources. This strategy reaches a state of diminishing returns under high resource conditions. Once individuals are satiated they benefit more from siblings’ survival than further resource monopoly (Drummond 2001; Hofer and East 2008). The size of a group of siblings (it is worth noting that they need not be from the same litter or clutch) is therefore a major influence on the level of siblicide which might be expected.

Life history strategies interplay with siblicide. If more offspring must be produced, with smaller resource investment relative to the needs of a creature, siblicide might be reduced, as the group must grow together to optimally disperse genes. If fewer offspring must be produced with greater resource investment relative to the needs of the animal, increased sibling competition may develop, leading resource-rich individuals to ensure monopolization of resources through siblicide (Pexton and Mayhew 2002).

The sequence in which a pair or group of siblings is born is entwined with their physical and resource-controlling dominance. In many siblicidal avian species, asynchronous hatching order permits first-hatched chicks to facultatively or obligately kill those which hatch later (Anderson 1990). Among humans, the correlation to birth order shifts across life stages. If both siblings are children, siblicide is more commonly practiced by older siblings, while among adults, siblicide is more commonly practiced by younger siblings. This change in relationship may be due to the relative difference in strength, particularly in a species where multiple births in the same cohort are relatively unusual (Gebo 2002). Most childhood sibling pairs will be asymmetrically matched in strength, with older siblings typically stronger. This difference would not necessarily

hold true in adulthood. Dominance roles appear to follow the same structure in other species (e.g., Hofer and East 2008).

Androgen levels positively correlate with competitive behavior, siblicide, and social dominance (Salmon & Hehman 2014). Siblings are often the first competitor an animal encounters. Competition for the resources a parent or alloparent can provide (e.g., food and shelter) may occur almost immediately after hatching/birth. As a result, a dominance hierarchy begins to form early in life. Among spotted hyenas (*Crocuta crocuta*), sibling ranking is decided before cubs emerge from the den, and the average age of siblicide is 47 days (Hofer and East 2008). Even earlier in life a behavior arguably under the category of siblicide is the adelphophagy exhibited by some shark species, where sharks will cannibalize their siblings in utero based largely on developmental status and size (Crespi and Semeniuk 2004).

Cannibalism appears to follow siblicide more frequently among fish, amphibians, and insects than birds and mammals (Mock et al. 1990). Cannibalistic siblicide serves to reduce competition as well as provide nourishment, while siblicide without cannibalism appears to be based upon resource monopolization and/or an escalation of sibling rivalries (e.g., Anderson 1990; Gebo 2002). Among some cannibalistic, siblicidal insects Hamilton's rule is followed, with less-related individuals killed and cannibalized preferentially over more-related individuals, suggesting that facultatively siblicidal systems may evolve such that the costs of siblicide are defrayed as much as possible while competition is reduced and nutrition directly gained via cannibalism (Dobler and Kölliker 2010).

## Conclusion

K- and *r*-selected life history strategies exist on a spectrum both among and within taxa. Siblicide is closely tied to K strategists, as it necessitates the allocation of more resources to fewer offspring. Though both parents and siblicidal offspring stand to lose fitness, the behavior can outweigh this cost with benefits of favoring stronger offspring more

likely to survive in uncertain conditions. When competition can be reduced by eliminating more distantly related rivals, this tendency evolves. Direct siblicide is more common in altricial species with limited mobility where full or half-siblings are the first rivals for resources encountered.

<sup>3</sup>Department of Psychology, University of Kentucky, Lexington, KY, USA

## Synonyms

Compulsive behavior; Conditioned responding; Maladaptive behavior; Pavlovian conditioning

## Definitions and Origins of Sign Tracking

Sign tracking refers to behavior that is directed toward a stimulus as a result of a learned association between that neutral stimulus and a biologically relevant object or event that is rewarding. The sign-tracking response develops even though reward delivery is not contingent upon a response. For example, following classic Pavlovian conditioning procedures, wherein a *conditional stimulus* (CS) is repeatedly paired with presentation of food reward (*unconditional stimulus*, US), it is often observed that the *conditional response* (CR) that develops consists of orientation to, approach, and/or engagement of the CS (i.e., the cue or “sign” that signals impending reward delivery). The term sign tracking was initially coined by Hearst and Jenkins (1974) to describe behaviors observed in pigeons during

“autoshaping” experiments. During these experiments, pigeons continued to peck a key light (CS) that had been paired with a food US, even when food availability was reduced (e.g., Brown and Jenkins 1968).

Animal studies have demonstrated that sign tracking occurs when a CS not only acquires an association with a US but also when it increases attraction and elicits a motivational state that exerts control over behavior. The latter is referred to as incentive salience, and the CS itself is referred to as an incentive stimulus (see Robinson and Berridge 2008 for review). An incentive stimulus is thought to evoke attraction, approach, and engagement, one that animals will work for and that invigorates reward-seeking.

Numerous studies with rodents have shown that there are considerable individual differences in animals that have the propensity to sign track to incentive stimuli (e.g., Saunders and Robinson 2013). For example, when a CS becomes associated with the receipt of food reward, for some rodents (sign trackers), the cue itself becomes attractive, eliciting approach and engagement with it. For these rodents, the CS becomes a potent conditioned reinforcer, and rats will work for it. For other rodents (goal trackers), the CS is equally predictive of reward, but they approach and spend time close to the location of reward delivery. For these rodents, the CS is relatively ineffective as a conditioned reinforcer. The predominant response of sign tracking to a CS, when reward is readily available, is considered to be a maladaptive behavior and has been extensively studied in the context of addictive behaviors. Such incentive salience attribution to reward-associated stimuli has been suggested as a mechanism that underlies the development and persistence of addictive behavior.

## Applications of Sign Tracking

Sign tracking has been associated with addictive behaviors such as binge eating, alcohol abuse, and drug addiction (for reviews, see Mathes et al. 2009; Tomie and Sharma 2013; Robinson and Berridge 2008).

Binge eating has been shown to be a direct result of a CS acquiring incentive salience in both animal and human studies (Mathes et al. 2009). Repeated pairing of a rewarding food (e.g., sugar) with a CS results in the CS acquiring the motivational properties of the reward. Therefore, when an individual is bombarded with stimuli that represent food reward (e.g., fast food signs), this stimulus renews food seeking (a measure of sign tracking) and also increases consumption, independent of hunger.

Similar to the compulsive behavior of binge eating, an alcohol cue can become more attractive and a more effective conditioned reinforcer in animals with a predisposition to sign track (Villaruel and Chaudhri 2016). In rodents, pairing a lever CS with the availability of ethanol produced significant sign tracking in some animals. Similarly, in humans, repeatedly pairing a favorite alcohol with a glass produced compulsive seeking and consumption of alcohol (Tomie and Sharma 2013). The glass became a motivating CS and renewed alcohol seeking and consumption even after tolerance and when “liking” of the alcohol’s effects were reduced. Therefore, in alcoholism, stemware and bar signs may transform into motivating CSs that produce alcohol-seeking behavior (sign-tracking behavior) in some individuals.

Decades of substance abuse research have demonstrated the relationship between substance use disorder behaviors and sign tracking. In humans, a CS (e.g., paraphernalia) associated with drug reward may instigate renewed craving and drug taking in the absence of the drug. This is often referred to as attentional bias (see Field and Cox 2008 for review). Attentional bias is measured by presenting an individual with drugs (e.g., cannabis and cocaine) paired with neutral visual drug-related stimuli (e.g., crack pipe). Attentional bias is the disproportionate amount of time spent looking at drug-related stimuli as opposed to neutral stimuli (e.g., stapler). This increase in time spent looking at drug-related stimuli presumably represents incentive salience and may be considered to be parallel to sign-tracking behavior of animals.

In rodents, animals that have been predisposed to sign track to a food CS are more motivated to self-administer cocaine and reinstate drug-seeking when primed with a drug cue than goal trackers (Saunders and Robinson 2013). Overall, these studies support that sign trackers may be more likely to attribute incentive salience to stimuli previously paired with a reward when compared to animals that do not sign track. As a consequence, sign trackers may be more vulnerable to the rewarding effects of drugs compared to subjects that do not sign track.

## Neurobiological Mechanisms of Sign Tracking

Recent research shows that animals that are predisposed to sign track have different “cognitive-motivational styles” and neurobiological mechanisms than animals that are not, i.e., goal trackers (Sarter and Phillips 2018; also see Kuhn et al. 2018 for review). Sign trackers appear to be sensitive to the influence of reward cues via enhanced bottom-up, cue-driven, dopamine-dependent processing, as a function of increased activity in the subcortical regions, including the striatum, amygdala, midline thalamus, and hypothalamus. In contrast, goal trackers appear to be less susceptible to the motivational properties of reward cues and also have greater executive (attentional) control over behavior that is mediated in part by the cholinergic system in the prefrontal cortex.

Several brain structures and neural pathways have been implicated in sign tracking, and sign tracking appears to be the result of multiple pathways and structures (Kuhn et al. 2018). For example, dopamine (DA) has been heavily implicated in the acquisition and maintenance of sign tracking, and these increases appear primarily in the NAc. However, DA in the NAc does not fully explain sign tracking as many other structures, monoamines, and hormones have been implicated in sign tracking. Future research is needed to investigate the relationship between these pathways and structures to better understand

how they work together to produce and maintain sign tracking.

## Signaller

Shannon M. Digweed  
Departments of Psychology and Biological Sciences, MacEwan University, Edmonton, AB, Canada

## Synonyms

[Manager](#); [Manipulator](#); [Sender](#)

## Definition

Any individual who produces a signal during the communication process.

There are many definitions of a signaller in the communication literature, which vary from manipulator to cooperative informer to continuous manager. Krebs and Dawkins (1984) provided a more manipulative view of the communicative process. They felt that signallers were “manipulators.” For example, in order for a communicative signal to persist in the environment, it must coevolve with a signaller and a receiver; therefore the manipulator's role is that of the sender or

signaller altering the listener's behavior in a way to directly benefit the sender (Krebs and Dawkins 1984). In a similar way to the definition of receivers, the definition of a signaller (as a manipulator) relies heavily on the fact that signals are reliable and provide honest cues that receivers can act upon. Thus, the handicap principle plays a key role in the idea of manipulation. Zahavi (1975) first introduced us to the idea of a costly signal by suggesting that in order for selection to continue acting on a communication process, both signaller and receiver need to benefit and thus have diverging interests. This divergence in interests, and the inherent cost associated with signalling, means that signals will honestly convey the required behavioral response to listeners (Zahavi 1975). Zahavi's ideas fit quite nicely with Krebs and Dawkins' (1984) suggestion that signallers have conflict with those around them and as a result manipulate that conflict through signalling.

Alternatively, the information view of communication suggests that signallers are intending to "inform" others in order to obtain a desired outcome (Smith 1977; Seyfarth et al. 1980). This viewpoint of a signaller relies heavily on more cooperative process that occurs when individuals' interests tend to overlap. Moreover this information sharing, with a cooperative view, requires special explanations for these somewhat unselfish acts (Morton 2017). Finally, information is a difficult behavioral feature to measure what exactly is the signaller conveying, is it intentional, and how can that be measured? Due to these inherent difficulties with a signaller transferring information, several other theories of signaller's behavior have arisen.

Morton (2017) and Owings and Morton (1998) suggest that the interaction between a signaller and receiver is one of regulations. The signaller, or manager, produces a signal that functions to regulate a particular situation. The behavioral result of that regulation will cause the signaller to "adjust" their behavior in return (Owings and Hennessey 1984). This means that from the perspective of the signaller, communication is an ongoing process that requires constant adjustment. In other words a

signaller's situation is constantly changing, and thus the management required to obtain the behavioral outcome from those around them is a constant process (Owings and Hennessey 1984). Furthermore, because the signaller is operating on the listeners' expectancies in a selfish way, signals do not need to have referents or information (Morton 2017).

Although these definitions focus primarily on the contributions of acoustic communication to the understanding of signallers, the definitional diversity is relatively consistent across communicative realms. Further research on the interaction of signaller and receiver in all communicative process will tease apart the divergent interests of these individuals and broaden our understanding of the role of a signaller.

## Simple Sequence Repeats

Calen P. Ryan  
Northwestern University, Evanston, IL, USA

### Synonyms

[Microsatellites](#); [Short tandem repeats](#); [STRs](#); [Variable number tandem repeats](#); [VNTRs](#)

### Definition and Introduction

Simple sequence repeats (SSRs), more often referred to as microsatellites or short tandem repeats, are short (1–9) tandemly repeated nucleotide sequences found ubiquitously across prokaryotic and eukaryotic genomes (Tóth et al. 2000). SSRs differ from minisatellite or satellite DNA, which consist of tandemly repeating sequences of 10–1000 and >1000 nucleotides, respectively. SSRs are highly mutable, individually variable sources of functionally relevant genetic variation, with applications in medicine, forensics, population and behavioral genetics, and evolutionary biology.

### SSR Composition and Genomic Distribution

SSRs are phylogenetically and genomically widespread, common to both prokaryotes and eukaryotes and occurring in subtelomeric, intragenic, intronic, and exonic regions (Tóth et al. 2000). SSRs often comprise large portions of host genomes and may be associated with known genic regions. The most common SSR units are mono- and dinucleotide repeats, but SSR unit length varies both by species and genomic location (Tóth et al. 2000). SSRs occur in both coding and noncoding DNA. Tri- and hexanucleotide repeats are more prevalent in exonic coding DNA, where they provide an important source of protein structural variability while maintaining reading frame. Poly (A/T) repeats tend to be more common than poly (C/G), but this also varies with genomic location.

While SSR variation in much of the genome is neutral, there is evidence for selection on repeat composition and length for many SSRs. In humans, trinucleotide CAG<sub>n</sub> motifs are overrepresented in exonic DNA, particularly in genes that code for proteins involved in neurodevelopment (Shimada et al. 2016). These CAG tracts, which code for the amino acid glutamine when expressed, may be evolutionarily favored at the level of the protein despite being under selection in DNA, and from their direct contribution to numerous human diseases (Shimada et al. 2016).

### SSR “Birth” and Evolution

The “birth” of SSRs involves de novo generation through conventional mutational processes (base-pair substitution and insertion-deletion events) or the modification of protomicrosatellites created during the dispersal of mobile transposable elements (Kelkar et al. 2008). Once formed, SSRs are hypothesized to change in length through replication slippage events, where disassociation of the replicating DNA strand is misaligned during reassociation (Viguera et al. 2001). While the genetic “stutter” caused by replication slippage is usually corrected by the DNA mismatch repair system, failure to do so can result in rapid

expansions or contractions in repeat number. The rapid expansion and contraction of SSRs lead to a great deal of mutability in repeat number in SSRs – up to 100,000x's higher than for point mutations within a given species. High mutation rates result in hypervariability in repeat length for many SSRs, making them an important source of genetic diversity (Tóth et al. 2000). For this reason, SSRs have been used extensively as genetic markers for population genetics, paternity tests, and forensic applications.

At the level of the population, SSR repeat number often resembles a bell-shaped – or occasionally a multimodal – distribution (Shimada et al. 2016). Such distributions could arise from a combination of opposing molecular and/or selective processes. Longer repeats become increasingly unstable and are more likely to accumulate additional repeats through replication slippage. Repeat expansion of SSRs also contributes to certain forms of protein toxicity and disease. However, slippage may result in the excision of numerous repeats in a single event, for example, through the creation and exclusion of DNA hairpin loops. Such instability results in the rapid expansion or contraction of many SSRs through time.

Given the inherently unstable nature of most SSRs, especially under conditions of cellular stress (Chatterjee et al. 2015), their prevalence is somewhat surprising. However, that same instability makes SSRs an important source of genetic diversity in challenging new environments, potentially facilitating adaptation, evolution, and speciation. These characteristics, combined with graded phenotypic effects of repeat number, have led to some researchers to refer to SSRs as “evolutionary tuning knobs” (King et al. 1997).

## Functional Consequences of SSR Variation

Both in vitro and in vivo studies have shown that repeat number for some SSRs can affect the binding of transcription factors or noncoding regulatory RNA, and/or alter protein form and function. These regulatory or conformational

changes can lead to a range of morphological, cognitive, and behavioral phenotypes. In *Drosophila melanogaster*, variation in a threonine-glycine repeat in the *period* clock gene affects circadian response to changes in temperature, a finding supported by clinal geographic variation in repeat length for this SSR among natural populations (Sawyer et al. 1997). SSR repeat length variation in genes involved in head development affect head shape in *Drosophila*, as well as in the stalk-eyed fly (*Teleopsis dalmanni*) (Birge et al. 2010). Notably, a significant genotype-phenotype association exists between several repeat motifs and eye-stalk length in *T. dalmanni*, a rapidly evolving trait under strong sexual selection in this species (Birge et al. 2010). The effect of SSR repeat length on morphological characteristics has also been demonstrated in other taxa, including mammals. Variation in repeat length for an SSR in the *Alx-4* gene is linked to polydactyly in both mice and the domestic dog, while variation in *Runx-2* seems to be partly responsible for interbreed variability in facial and cranial structure among domestic dogs (Fondon and Garner 2004).

A number of behavioral phenotypes have also been shown to vary with variation in SSR repeat number. A polymorphic SSR in the *arginine vasopressin 1a receptor (avpr1a)* gene is associated with differences in this receptor's binding affinity for vasopressin and is linked to both inter- and intraspecific differences in social behavior in among voles (Hammock and Young 2005). Similar variation in the *avpr1a* gene may correspond to sociosexual differences between Chimpanzees (*Pan troglodytes*) and Bonobos (*Pan paniscus*), and may contribute to autism-associated sociobehavioral deficits in humans. Other genes with nearby or intervening SSRs that have been associated with behavioral and cognitive phenotypes include genes coding for the serotonin transporter (SLC6A4), the dopamine transporter (SLC6A3), the dopamine receptor (DRD4), and the androgen receptor (AR). SSR variation in a polyglutamine tract in the human AR has also been associated with a range of morphological and behavioral phenotypes, and is a risk factor for several diseases.

## SSRs and Human Disease

Over 40 human diseases, referred to as “repeat expansion disorders,” have been linked to pathological SSR expansion. These disorders include Huntington’s disease, myotonic dystrophy, spinal and bulbar muscular atrophy, fragile X, and a number of spinocerebellar ataxias. The link between repeat number and disease include polyglutamine toxicity, altered RNA/protein levels, and protein gain/loss of function. Typically, symptom severity increases and age at onset decreases as repeat number expands with each generation. SSRs with longer repeat lengths are less stable and accumulate additional repeats more rapidly than shorter repeats. As a result, disease symptoms may arise at an earlier age with each generation, a process referred to as “anticipation.” Notably, a disproportionate number of repeat expansion disorders are neurological in nature. Some researchers have argued that highly mutable SSRs may have played a fundamental role in the rapid evolution of brain and cognitive development in the human lineage, while also bearing a burden in the form of a susceptibility to a number of neuropathological diseases (Shimada et al. 2016).

## Conclusion

The biological significance of SSRs arises from their ubiquity, mutability, and molecular and phenotypic effects. While the pathways through which SSRs can affect health, behavior, and evolution are becoming clearer, the causes and consequences of repeat variation for the majority SSRs are still unknown. Rapid technological and analytical developments will no doubt improve the scale and resolution of data necessary to answer these questions, and aid in elucidating the role of SSRs in gene regulation, phenotypic variability, and evolution.

[Point mutation](#)

## Definition

SNPs are single nucleotide changes in genomic DNA at which different nucleotides occur in different individuals of a population. Each nucleotide at such a position denotes an allele of the SNP.

## Introduction

Single nucleotide polymorphisms (SNPs), pronounced as “Snips,” is the common type of variation found in DNA between genes (Genetics Home Reference). Each SNP differs by a single DNA block represented as nucleotide. For example, a SNP may be replaced by adenine (A) in place of guanine (G) in a stretch of DNA. SNPs, if falling under coding region of genes, do not alter the amino acid sequence and, in turn, the sequence of protein produced. They are classified into two parts: synonymous, i.e., genes that do not bring any change in protein, and nonsynonymous, i.e., genes that bring change in amino acid sequence, which may be a missense (resulting in incorrect amino acid) or nonsense (not coding for any amino acid).

SNP density of existence can be predicted by the sequence known as microsatellites. The most common predictor of density is “AT” microsatellites. SNPs are also classified on the basis of their regions, i.e., noncoding and coding regions. Coding regions can be further classified as missense and nonsense regions. SNPs represent 90% of the total variations, which means that the genetic variation occurring on a daily basis is caused by small change in nucleotide.

## Identification

Single base variants in cDNA are considered as SNPs, as are single base insertions and deletions in the genome. Several different methods have been developed to discover SNPs. A simple procedure is to analyze the sequence data stored in the major databases and identify the SNPs. DNA chips/microarray has been developed for SNPs

identification. When the complete base sequence of a segment of DNA is considered, one can identify four alleles represented by A, T, G, and C at each SNP locus in the segment.

It is estimated that approximately 90% of sequence variation in human is due to SNPs. Our genome is estimated to contain 3–17 million SNPs. Of these, 5% of SNPs are expected to occur in genes. Thus, SNPs provide a molecular marker that occurs in genome at a very high density and can therefore be used to map genes involved in human diseases.

Efforts are being made to use SNPs to map hundreds or thousands of genes that have an effect on the safety and efficacy of various drug treatments. These SNPs can be placed on gene chips that can be used to genotype individuals for those genes involved in response to specific drugs. Based on this data, more efficacious and safe treatment can be selected for these individuals. For example, variants in the gene encoding apolipoprotein E were found to be correlated with variation in response to a drug used for treatment. Gene apoE is involved in susceptibility to Alzheimer's disease, and a cholinesterase inhibitor is used to mitigate the disease symptoms (Wilkinson et al. 2004).

## Diseases

SNPs can be treated as a biomarker for different diseases like sickle cell anemia,  $\beta$ -thalassemia, and cystic fibrosis. Heart disease, diabetes, and cancer can also be correlated with SNPs. They work in coordination with other SNPs to produce a disease condition like in osteoporosis (Singh et al. 2010). Higher risk of cancer is associated with SNPs in noncoding regions, and mRNA structure and disease susceptibility may be affected. Such synonymous substitutions do not result in a change of amino acid in the protein but can still affect its function in other ways. For example, multidrug resistance gene 1 (MDR1) can cause the mutant pump to be less functional (Kimchi et al. 2007).

Nonsynonymous substitutions include missense in which single change in the base results

in a change in an amino acid of protein and its malfunction leads to disease (e.g., c.1580G>T SNP in LMNA gene mandibuloacral dysplasia and progeria syndrome, Al-Haggar et al. 2012) and nonsense, which includes a premature stop codon or a nonsense codon in the transcribed mRNA. A usually nonfunctional protein product is obtained if point mutation occurs in a sequence of DNA (e.g., cystic fibrosis caused by the mutation of G542X in the cystic fibrosis transmembrane conductance regulator gene, Cordovado et al. 2012).

## Importance of SNPs

Human genetic variation occurs primarily by SNPs occurring in protein coding regions, which contribute to different phenotypic variations. SNP (rs2596542C/T) in major compatibility genes can be used as a good potential biomarker in assessment of liver disease (Mohamed et al. 2017). SNPs are critical in predicting prostate cancer risk. Studies suggest that there is strong dose-dependent association. SNPs provide the way for therapeutic targets. SNPs are also found to be very useful biomarkers in plant breeding and genome analysis. Eleven SNPs are found to be reported at nine loci for gastric cancer risk.

## Examples Are as Follows

- (a) Serotonin 5-HT<sub>2A</sub> receptor gene rs6311 and rs6313 are SNPs on human chromosome 13 (Giegling et al. 2006).
- (b) Leiden thrombophilia was caused by Factor V in the F5 gene in SNPs (Kujovich 2011).
- (c) CRP gene on human chromosome 1 rs3091244 is an example of a triallelic SNP (Morita et al. 2007).
- (d) DNA mismatch repair gene PMS2 (rs1059060, Ser775Asn) is an intronic SNP and is associated with increased sperm DNA damage and risk of male infertility (Ji et al. 2012).

## Databases

SNP database named dbSNP is from the National Center for Biotechnology Information (NCBI). Till 8 June 2015, dbSNP identified 149,735,377 SNPs in humans. Kaviar is an anthology of SNPs from multiple data sources including dbSNP (Glusman et al. 2011). OMIM database (diseases are represented in text form) dbSAP – single amino-acid polymorphism database – is used (Cao et al. 2016).

## Programs for Prediction of SNPs

A change in amino acids with almost similar size and physicochemical properties (e.g., substitution from glycine to alanine) has a mild effect. SNP can disrupt secondary structure elements (e.g., substitution to proline in an alpha helix region), and such mutation usually may affect the whole protein structure and function. Therefore, a group of programs for the prediction of SNP effect was developed which includes SIFT, SNAP2, SuSPect, PolyPhen-2, Predict SNP, Mutation Taster: official website, and Variant Effect Predictor from the Ensembl Project (Wei et al. 2010).

## Evolutionary Relationship

Variations occurring in a human population in the SNP allele, common to one geographical area, will rarely be found in another. Therefore, for a population, SNPs can have a minor allele frequency, and the lowest allele frequency at a locus can be observed in a particular population. Therefore, SNPs can be used in an investigation or study of any migration patterns.

## Conclusion

SNPs occurring in different populations help in better understanding the metabolism of lipids and thus reducing the cardiac risk. Polymorphism

associated with LDL correlated with lipid metabolism is associated with reduction in rate of myocardial infarction. The clinical setting and evaluation of polymorphism in different populations will play a role in the future for coronary artery disease. SNPs can be used as genetic biomarkers for the family Brassicaceae. The species named *B. rapa* was used to successfully genotype the Brassicaceae, and many more markers are genotyped. SNPs are acting as a key to unlock the mystery. With advancement in fields like biotechnology, many of the so-called mysteries have been resolved, which help in prevention and treatment of various diseases and will ultimately lead to the discovery of new drugs, which can increase the average life span of human beings. Living conditions and human lifestyles are improving day by day; therefore, with the advancement in biotechnology, safer anticancer drugs will come.

## Definition

Food and feeding habits of the four extant species of the order Sirenia (dugongs and manatees).

## Introduction

The order Sirenia is comprised of the two families Dugongidae and Trichechidae. Dugongidae has only one living member, the dugong (*Dugong dugon*). The most recent relative of the dugong, the Steller's Sea Cow (*Hydrodamalis gigas*), was hunted to extinction shortly after its discovery in the mid-1700s (Domning 2016). The dugong is presently listed as vulnerable by the International Union for Conservation of Nature (IUCN) Red List, though it is considered extinct in some portions of its range and endangered or critically endangered in others (Marsh and Sobotzick 2019). The closest living relatives of the dugong are the manatees, in the family Trichechidae. There are three extant species of manatee: the African manatee (*Trichechus senegalensis*), the Amazonian or South American manatee (*Trichechus inunguis*), and the West Indian manatee (*Trichechus manatus*). All three species are presently listed as vulnerable by the IUCN Red List (Deutsch et al. 2008; Keith Diagne 2015; Marmontel et al. 2016). However, the two subspecies of the West Indian manatee, the Antillean

manatee (*Trichechus manatus manatus*) and the Florida manatee (*Trichechus manatus latirostris*), are each listed as endangered (Deutsch et al. 2008). The biggest threats to all these species are illegal hunting, habitat loss, and anthropogenic factors such as boat strikes (Deutsch et al. 2008; Keith Diagne 2015; Marmontel et al. 2016; Marsh and Sobtzyk 2019).

The members of the order Sirenia have long been considered the only marine mammal herbivores and have developed some unique adaptations that allow them to fill this niche. Perioral bristles, specialized vibrissae, on the upper and lower lips in combination with facial muscles help maneuver food into the mouths of these animals. In dugongs, this is a simpler manipulation that moves food into the sides of the mouth, whereas in manatees there is a prehensile grasping action that allows them to manipulate the food into the front of the mouth (Marshall et al. 2003). These bristles are also used to touch and explore what is around an individual, possibly searching for additional food. In addition to the bristles, the flippers can be used in feeding as well as to clean the bristles after feeding or exploring (Marshall et al. 2003). Palatal pads, horny layers of skin located rostral to the cheek teeth, are thought to aid in the mastication of sea grasses and other plants (Marshall et al. 2003). Manatees have also evolved what is known as horizontal tooth replacement. In this process, the worn anterior most teeth are lost, and as the tooth row moves forward, new teeth erupt in the posterior most position of the tooth row. It is thought that this adaptation arose because of their herbivorous diet and the wear it places on the teeth of these animals (Beatty et al. 2012; Domning 1982). This adaptation is not seen in dugongs, instead their teeth have open roots and they have longer and more robust palatal pads than manatees, both of which are thought to help extend the life of the teeth. (Domning 1982; Marshall et al. 2003).

Sirenian diets are not well-known as they are often in environments where their behaviors are difficult to observe. They have very large ranges, and some individuals migrate extensively within this range. Due to these factors, the complete diet of these animals throughout the whole of their

range is unknown and will vary depending on the season, location, and plant distribution. Many of the studies that have been done have attempted to evaluate diet composition between age classes and seasons at their study locations.

### **African Manatee (*Trichechus senegalensis*)**

Found primarily along the west coast of Africa and ranging from southern Mauritania through Angola, the African manatee inhabits coastal marine waters and adjacent freshwater rivers and lakes as well as lagoons and brackish estuaries and will move between these different environments (Keith Diagne 2015). Despite protection throughout its range, poaching remains one of the biggest threats to this species (Keith Diagne 2015; Reeves et al. 1988). Habitat loss is also a major threat. Genetic diversity and population size are likely to be impacted by habitat degradation and fracturing due to the construction of dams. However, due to a lack of long-term committed funding, remoteness of habitats, as well as their extensive range, little is known about this species (Keith Diagne 2014, 2015). Much of what is known comes from indigenous knowledge of their range, habitat, abundance, and behavior (Reeves et al. 1988). However, efforts are being made to further African manatee conservation training with workshops aimed at empowering African biologists and community members to begin manatee research and conservation activities (Keith Diagne 2014, 2015).

Due to the African manatees' extensive range and diverse habitats, it is likely that feeding strategies vary widely among these habitats. In Sierra Leone, African manatees have been observed eating elephant grass (*Pennisetum purpureum*) though they have been reported to consume fish and rice, creating conflicts with local stakeholders. Because of this tension between the locals and the manatees, those who capture or hunt these animals are seen as performing important services to the community (Reeves et al. 1988). Further north of the study conducted by Reeves et al. (1988), the leaves and fruit of

mangroves have been found to be an important food source for this species, demonstrating the fluidity in the manatees' diet relative to habitat and food availability. Reeves et al. (1988) is not the only study to have found that the African manatee is not strictly herbivorous, as was once thought. Alternatively, Keith Diagne (2014) demonstrated that African manatees eat more than just plants, and that their diets do not change significantly over the course of the animals' lifetime. In Gabon, manatees consume primarily flowering plants including hibiscus (*Hibiscus tiliaceus*), lotus (*Nymphaea lotus*), and knotweed (*Polygonum salicifolium*). Some grass species, including hippo grass (*Vossia cuspidate*), were also determined to be part of their diet. In addition to plants, an average of 10% of the animals' diets, depending on location and age, consisted of hermit crab (Keith Diagne 2014). In Senegal, the manatees' diets consisted of approximately 50% fish, mollusks, and bivalves, depending on location and season. The remainder of their diet was plant-based, consisting mostly of grasses from the genus *Echinochloa* and water nymph (*Najas guadalupensis*) (Keith Diagne 2014). While diet comparisons between manatees in Senegal and Gabon showed similar proportions of aquatic and terrestrial plants, historical data indicates that diversity in the African manatees' diet has decreased significantly in the last 70 years. This change is likely an artifact of anthropogenic climate change and habitat loss (Keith Diagne 2014).

### Amazonian Manatee (*Trichechus inunguis*)

The Amazonian manatee is the only extant Sirenian with an exclusively freshwater habitat. They inhabit most of the Amazon River basin from the headwaters to the mouth of the river and can be found in all three types of water, which are characterized by nutrient levels and water transparency: white, black, and clear. They appear to be more abundant in the white, nutrient-rich water, but there are currently no reliable population estimates. It is believed the population may be

stabilizing in some regions due to local awareness and conservation efforts, but overall, the population is still decreasing. Because these animals engage in long seasonal movements, they can migrate out of protected areas to places where they are more vulnerable to hunting pressures (Marmontel et al. 2016). Some indigenous peoples, including the Siona in Ecuador, have self-imposed bans on hunting due to low population levels. Indigenous knowledge is a great source of information for holistic conservation efforts as they are aware of where manatees can be found and some of the plants they feed on, knowledge that is harder for scientists to acquire due to the secretive nature of the manatee (Timm et al. 1986).

Much of what is known about the Amazonian manatee diet, if not acquired from speaking with indigenous peoples and hunters, has been determined from analyzing floating fecal samples and stomach contents of manatees that were hunted or otherwise killed in the areas of study. Guterres-Pazin et al. (2014) identified 49 plant species consumed by the Amazonian manatee, a large portion of which had not been previously cited in the literature. Even so, there were species mentioned by the local peoples that were not seen in this study. Grasses from the family Poaceae were seen with the highest frequency in multiple studies (Colares and Colares 2002; Guterres-Pazin et al. 2014). The importance of a particular species or habitat of plant species (emergent, free-floating, fixed-floating, etc.) varies by season and location (Colares and Colares 2002; Guterres-Pazin et al. 2014; Timm et al. 1986). The Amazonian manatee seems to be opportunistic and will consume a large variety of plant species. The number of species consumed seems to be consistent between flood and drought seasons, but the actual species will vary (Guterres-Pazin et al. 2014). However, Best (1983) hypothesized that in years of extreme drought, where the water levels drop so low that plants are unavailable to the animals, the manatees may enter a fasting state until the water level rises, making plants available again. While eating their preferred plant species, it seems as though there is accidental ingestion of arachnids, zooplankton, plant seeds, sand, and

other unidentified materials. The invertebrates were found intact and undigested, indicating they are not a nutritional supplement for the animals, unlike the plant seeds which were broken open and may represent an additional nutrition source (Guterres-Pazin et al. 2012). Crema et al. (2019) found that individual diet does not seem to vary over time, with the exception of lactating females who, it was hypothesized, either move to different foraging grounds or change their diet preferences while lactating, possibly due to the higher energetic demands of the animal. It is possible that the stable isotope analyses used in this study, due to their long-term nature, may mask the seasonal diet shifts seen in other studies.

### West Indian Manatee (*Trichechus manatus*)

The Florida manatee is found primarily in the warm waters of the Florida peninsula, inhabiting freshwater rivers, brackish estuaries, and coastal marine environments. Members of this subspecies have been known to move between these different environments, traveling as far north as Virginia and as far west as Texas in the summer months. Some will even travel south to the Bahamas. In the winter, they return to the warm waters of Florida, generally to the same refuge each year. The biggest threat to this subspecies is watercraft collision followed by other human-related causes of mortality such as habitat loss (Deutsch et al. 2008). The Antillean manatee can be found in and traveling between freshwater rivers, brackish estuaries, and coastal marine habitats from the Bahamas to Brazil including areas of the Caribbean Sea and the Gulf of Mexico and was historically documented in 41 countries within that range. Recent assessments show manatee populations in 20 countries with individuals sighted in additional countries. However, the distribution of these populations is not continuous. The main threats to this subspecies are hunting and habitat loss (Deutsch et al. 2008).

The West Indian manatees are opportunistic feeders and seem to feed on whatever vegetation

is available. However, stable isotope analyses indicate that seagrasses are an important part of the diet of these manatees in most areas of their range (Alves-Stanley et al. 2010; Reich and Worthy 2006). Which species of seagrass are most important to the diet seem to vary by location of the individual. Castelblanco-Martínez et al. (2009) found that in Mexico the seagrasses *Halodule wrightii* and *Thalassia testudinum* were the most important, whereas Allen (2014) found that in Belize, rhizomes and only the seagrass *Halodule wrightii* were most important. Though other seagrasses were consumed in Belize, they were not as prevalent in the collected samples. In addition to seagrasses, when available, mangroves and algae species can contribute significantly to diet. The significance of that contribution varies by location and availability (Allen 2014; Castelblanco-Martínez et al. 2009). Like in the Amazonian manatee, it is speculated that there is accidental ingestion of invertebrates while consuming their preferred food of aquatic plants (Allen 2014); however, there have been several documented cases of the West Indian manatee feeding on fish, sponges, and other invertebrates. In 1976, fishermen reported manatees stripping the flesh off of fish caught in stationary gill nets off the coast of Jamaica (Powell 1978). Also, multiple observations were made from 1992 to 2017 of manatees feeding on the sponge *Condrilla caribensis* off docks, pylons, and other hard surfaces in the Florida Keys (Fitt 2020). While it is not known how much this contributes to the diet of the West Indian manatee, it is unlikely that it is a large portion like in the African manatee.

### Dugongs (*Dugong dugon*)

The dugong is the only strictly marine Sirenian inhabiting tropical, coastal, and island waters of at least 37 states and territories between East Africa and Vanuatu. Within this range, the areas with the largest subpopulations of dugongs are in Australia, Bahrain, Papua New Guinea, Qatar, and the United Arab Emirates (Marsh and

Sobtzick 2019). Like the African manatee, dugongs are protected throughout most of their range, but there is little enforcement of these protections. The biggest threats to the dugongs are from hunting, incidental capture, boat strikes, habitat loss, and threats to seagrass (Marsh and Sobtzick 2019).

Dugongs primarily feed on seagrasses and their rhizomes. Because of their feeding style, consuming plants in a muzzle wide serpentine path on each dive, they are unable to feed selectively on the individual plant level, but instead consume species at equal rates according to their proportions within the meadow being grazed (Preen 1995b; Tol et al. 2016). Tol et al. (2016) found that while *Halophila ovalis* and *Halodule uninervis* were the most common species at all sites studied in Queensland, biomass was the most important factor in dugong feeding patterns. That is, dugongs primarily fed at locations of high biomass regardless of species composition. However, Preen (1995b) found that dugongs seem to have a preference for the species *H. ovalis* and *H. uninervis*, and intense grazing of sea grass beds can encourage the growth of these pioneer species while slowing the growth of the less preferred species of *Halophila spinulosa* and *Zostera capricorni*. In Papua New Guinea, Johnstone and Hudson (1981) found that seagrasses, preferentially *Thalassia hemprichii* the most abundant in the area, made up about 97% of dugong diets with algae making up the rest, though the mouth sample of one dugong in the study consisted solely of mangrove leaves, indicating this may at times be a supplementary diet to seagrasses when available. It was thought that, like manatees, dugongs accidentally ingest invertebrates while consuming seagrasses; however, Preen (1995a) found that in some areas dugongs deliberately feed on ascidians, or sea squirts, which make up a significant portion of the dugongs diet in these areas.

## Conclusion

There are several hypotheses as to why manatees and dugongs, previously thought to be strictly

herbivorous, may intentionally feed on invertebrates and fish. The main hypothesis is the lack of nitrogen in their diet of aquatic plants (Fitt 2020; Preen 1995a). Another hypothesis was that manatees choose these other food sources when plants are unavailable, but several studies presented here seem to disagree with this hypothesis (Keith Diagne 2014). In addition to the extant species of today, at least one extinct species of Miocene Trichechid is believed to have had a diet consisting of shellfish (Keith Diagne 2014).

Historically, however, the fossil record seems to indicate that sirenians have been dependent on seagrass as a food source since their appearance in the Early Eocene (Domning 1981). It is hypothesized that the evolution of horizontal tooth replacement in manatees allowed them to outcompete members of the Dugongidae family in the New World (Domning 1982). Further niche partitioning is hypothesized to be related to rostral deflection which can influence where in the water column an animal is most adapted to feed. Dugongs have the highest degree of deflection, which is useful for bottom feeding. African and Amazonian manatees have the lowest degree of deflection, which allows them to feed on floating vegetation and may reflect a scarcity of submerged plants in their habitats. West Indian manatees have a degree of deflection between the two extremes allowing them to opportunistically feed on both floating plants and submerged plants (Domning 1982; Marshall et al. 2003).

Despite all that seems to be known, more information is needed about the diets and foraging habits of these last species of the order Sirenia in order to protect and improve protections of these species and their preferred habitats, thus ensuring their survival.

[Dugong movement](#); [Manatee movement](#); [Sea cow ambulation](#); [Siren locomotion](#)

## Definition

Movement used by members of the order Sirenia (e.g., manatees and dugongs) to transverse their environment.

Sirenia is a small order that consists of four species from two families, Dugongidae (dugong) and Trichechidae (manatees). The sirenians received their name from the mermaids of Greek mythology known as sirens (Berta et al. 2015). Globally, all four species are considered to be in danger of extinction (Marsh et al. 2012).

Sirenians have streamlined, torpedo-shaped bodies with short necks and thick skin. They possess short, rounded paddle-like flippers used for steering, ambulation, and feeding, a horizontal

tail fluke, and no dorsal fin (Berta et al. 2015; Domning 2014). Sirenian bones show pachyostosis, or bone thickening, and osteosclerosis, or an increase in compact bony tissue. These features influence buoyancy during swimming (Domning 2014). Manatees are characteristically smaller than dugongs and have relatively rounder tails and a less pronounced snout (Berta et al. 2015).

All sirenian species are found in tropical and subtropical waters. The dugong (*Dugong dugon*) is the most widely distributed siren, commonly found in the shallow coastal bays of the Indian Ocean and western Pacific Ocean. On the other hand, manatees are coastal animals localized to specific rivers and oceans. They can also be found transitioning between continental shelf waters, such as in the Caribbean Sea. The West Indian manatee (*Trichechus manatus*) and Amazon manatee (*Trichechus inunguis*) reside in the western Atlantic Ocean. The African manatee (*Trichechus senegalensis*) is found in the eastern Atlantic Ocean ranging from Senegal to Angola (Forcada 2018).

Sirenians are the only group of fully aquatic herbivorous mammals. An individual must consume approximately 4–25% of its body weight per day to carry out basic functions. Dugongs feed almost exclusively on seagrass on the sea bottom, while manatees have a more variable diet. The West Indian manatee feeds on more than 60 species of freshwater, marine, and terrestrial plants, while the Amazonian manatee feeds on emergent freshwater plants (Hines et al. 2012). Cooler water temperatures and dietary restrictions limit the latitudinal distribution of sirenians to tropical and subtropical regions (Marsh et al. 2012).

Earliest known sirenians were quadrupedal and capable of terrestrial locomotion. The fossil record shows Sirenia first appearing in the late early Eocene of Africa with more diversity among the order appearing by the middle Eocene. The earliest ancestors were pig-sized, four-legged, and amphibious with well-developed legs (Berta et al. 2015; Domning 2018). However, their semi-aquatic lifestyle can be deduced by the discovery of dense, swollen pachyostotic ribs found within lagoon deposits

(Berta et al. 2015). By the end of the Eocene, Dugongidae appeared with a modern sirenian shape beginning to take form: fully aquatic, streamlined body, flipper-like front legs, no hind legs, and powerful horizontal hind fin. The Trichechidae were the last to evolve during the Eocene most likely from Dugongidae or other earlier ancestors (Domning 2018).

## Swimming

While manatees and dugongs belong to the same order, they employ different methods of swimming. Manatee locomotion utilizes a dorsoventral undulation of their wide, flat tail, which predates the use of the wing-like caudal fluke employed by the dugong. The fluke and body create a dorsoventral undulation that produces sinusoidal waves. The wave amplitude increases as it traverses the length of the body. Due to the use of primitive dorsoventral undulation in conjunction with their larger frame, fluke size, and wide absence of developed peduncular muscles, manatees are regarded as ineffective swimmers (Kojaszewski and Fish 2007).

Marine animals that utilize an undulatory method can be characterized as anguilliform, subcarangiform, carangiform, or thunniform. This characterization is determined by the posterior nature of the generated propulsive wave. Anguilliform swimmers create the smallest posterior wave, followed by subcarangiform, carangiform, and thunniform, respectively. Thunniform swimmers create the most posterior waves and move at higher speeds than subcarangiform swimmers, such as manatees. Subcarangiform swimmers create a wave rostrally across their body length as compared to the other swimming modes and have a fusiform body and a deep caudal peduncle. A small amplitude wave is created at the cranial end of the subcarangiform swimmers to counterbalance transverse waves and improve swimming efficiency. Manatees are considered to be less economical swimmers as they create less thrust power than other animals that use other swimming modes (Kojaszewski and Fish 2007).

In comparison to the manatees, the dugong is a fast swimmer due to its more economical oscillating wing-like caudal tail. This is evident as dugongs are more active in their daily movements and have an average speed of 2.7 m/s compared to the manatee's average speed of 0.6–0.8 and 0.8–1.89 m/s during migration. Dugongs are characterized as thunniform or carangiform swimmers (Kojaszewski and Fish 2007).

## Manatee “Swim-Walking”

Locomotor studies of the sirenians have primarily focused on tail-driven swimming biomechanics (see above) while largely ignoring the pectoral flippers. Kojaszewski and Fish (2007) describe the pectoral flippers of the manatee as being “held motionless against the body” during swimming. Behavioral observations of captive individuals reveal that manatees use their pectoral flippers to steer themselves while swimming, to anchor themselves to the seabed while feeding, and to guide food to their mouths (Horikoshi and Schulte 2006; Kikuchi et al. 2010). Additionally, Horikoshi and Schulte (2006) reported, but did not fully elaborate on, the presence of “swim-walking” as part of the daily behavioral repertoire of captive manatees at Homosassa Springs Wildlife State Park, Florida. During “swim-walking” the flippers remain mostly vertical, and slight protraction and retraction allow the animal to move forward in a stepwise fashion keeping in contact with the substrate below the manatee. Tail-driven propulsion is active during “swim-walking,” and this most certainly remains the primary form of forward thrust. It is unclear whether the forelimbs support any aspect of the animal's underwater body weight or provide any propulsive or braking forces. Significant force production is unlikely considering musculature of the pectoral flippers is thin and reduced (Dawson et al. 2000). As with other benthic walking species (Lucifora and Vassallo 2002), it is likely that manatees use “swim-walking” for more control and maneuverability for purposes of foraging. In this entry, we analyzed the gait sequence of “swim-walking” in a single West

**Sirenia Locomotion, Fig. 1** Representative cycle demonstrating forelimb “swim-walking” in manatees. Duty factor varies considerably, but across most cycles ( $n = 10$ ) is ~60% of a stride

Indian manatee (*Trichechus manatus*). During “swim-walking” the left and right forelimb contacted the substrate in an alternating, rather than paired punting, pattern. The duty factor, or the percentage of the time the flipper is on the ground, is approximately 60%, but this varies considerably across strides ( $n = 10$ ) (Fig. 1). The alternating left/right movement of the limb indicates that manatees are likely utilizing conserved neuromuscular patterns retained from quadrupedal ancestors (Domning 2001).

## Migrations

Another critical component to sirenian locomotion is how their locomotor preferences assist in moving about their environments through mass migration. Although some species have more individualized migration preferences, most species typically follow a set of general themes. Patterns of migratory behavior have been observed to be based mainly on seasonal conditions. Both dugongs and manatees have a preferable water temperature range in which they populate with problems arising when there is a deviation in ideal temperature. Specifically, sirenians prefer to travel to areas of warmer water when cold

seasons affect their locations. For example, it has been identified that dugongs are sensitive to water temperatures below approximately eighteen-degree centigrade (Sheppard et al. 2006).

Sirenians make long seasonal trips to locations that possess warmer waters during cold seasons. Once the cold season has passed, they return to their original habitat that has since rewarmed to an ideal temperature. For example, Florida manatees exhibit this behavior when migrating south in late autumn or early winter and returning in late winter or early spring (Deutsch et al. 2003). Although sirenians follow the basic principle of seasonal migration, migratory distance depends on multiple factors including sex and individual preference. Deutsch et al. (2003) reported that during their seasonal migration, male manatees covered more daily distance than females, and females were observed to be more sedentary than their male counterparts. It has also been observed that some manatees may not follow sex norms and travel at their own distinct migratory paces. Marsh et al. (1992) reported that tidal amplitude, which takes into account the current sea level of the area, has been seen to influence migratory behavior in dugongs. Tidal amplitude is essential for daily movements and behaviors (Marsh et al. 1992). Although a variety of factors tend to

impact the migratory behaviors of sirenians, it can be concluded they actively migrate to seek warmer climates during colder seasons.

## Sirenian-Human Interaction

Manatees and dugongs are in mortal danger when they come into contact with watercrafts. Additionally, the collisions could pose a danger to those aboard the vessel if significant damage results from the impact. These incidents have negative impacts on both sirenian and human populations. A study monitoring a group of tagged manatees observed that manatees spend 78% of their time near the surface of the water in the observation area (Edwards et al. 2016). The preference to be close to the surface of the water would place manatees at greater risk of being struck by a human craft.

Innovations that cause sirenians to divert away from approaching vessels could prevent lethal sirenian-human interactions. It was seen that sonar alarms emanating a certain frequency could lead to the avoidance of retrieving dugongs in fishing nets. McPherson et al. (2004) were able to observe that a sonar alarm emanating a frequency of 2.9 kHz was sufficient to cause a “cautious active avoidance response by dugongs.” The dugongs moved away from the nets that emanated the frequency. The findings are a clear sign that more research within this particular field is needed, as it could provide a better understanding of how humans can have a beneficial impact on sirenian behavior and locomotion.

## Conclusion

This entry explores the unique locomotion of sirenians and their interactions with humans. Modern sirenians are fully aquatic mammals that utilize dorsoventral undulation to transverse their environment. Sirenians also employ a form of walking that is primarily used for feeding and has not been thoroughly studied. Their locomotion is best exemplified when studying migration to warm

water when their habitat water temperature decreases. Due to their slow movement and preference to remain close to the water’s surface, human interactions can cause sirenian fatalities. Potential human innovations are arising to prevent lethal contact, such as releasing a frequency to alert sirenians to watercraft.

## Sirenia Morphology

Debra P. Moore

The Institute for Marine Mammal Studies  
(IMMS), Gulfport, MS, USA

## Synonyms

Order sirenia; Sea cow

Common Name: Manatee and Dugong

## Introduction

Sirenians derived their name from the Greek mythological name, sirens, believed to have its origin from lonely sailors confusing these marine mammals with mermaids. They are also known as sea cows as their diet is primarily herbivorous composed of submerged sea grass and floating or emerging vegetation. Some species can on

occasion eat fish or crustaceans. They spend a large part of their day eating and are slow moving, nonaggressive animals.

They have sparse hair over their body, mammary glands tucked under their pectoral flippers used to nurse their calves for 18 months or more, are warm blooded, and breathe air.

Modern-day sirenians contain two genera: *Trichechus* (manatees) which live in tropical or subtropical waters of the Americas within primarily the Gulf of Mexico, Atlantic, Caribbean, Amazonian rivers, and West Africa and the *Dugong* found in the Indian and Pacific Ocean (Velez-Juarbe et al. 2012).

There are three species of manatees: *Trichechus inunguis*, Amazonian manatee; *Trichechus manatus*, West Indian manatee; and *Trichechus senegalensis*, West African manatee. There is one extant species of dugong, *Dugong dugon*, and one extinct species, the Steller's sea cow (*Hydrodamalis gigas*). Man hunted the Steller's sea cow to extinction in the eighteenth century only 30 years after they were discovered in Arctic waters (Velez-Juarbe et al. 2012).

## Evolution

Sirenians likely evolved aquatically more than 60 million years ago (Eocene era) from terrestrial quadrupedal mammals. Their closest living land relatives today are Proboscidea (elephants) and Hyracoidea (hydraxes) (Domning 1994). They are completely distinct in their evolution from other marine mammals (Cetacea and Pinnipedia).

## Functional Morphology

### General

Manatees and dugongs are primarily gray in color and have robust thick fusiform-shaped bodies ideal for swimming and propelling through water using their horizontally flattened tail. Through evolutionary development, there was no need to have hind limbs in water; thus, they were eliminated and the pelvis was reduced to a small vestige. Manatees' tails are wide rounded

paddle shaped, and dugongs are fluke-like with lateral projections on their distal ends similar in shape to whales.

Manatees are generally larger than dugongs with adults reaching a mean length of approximately 3 m (9–10 ft) and an average weight of 410–545 kg (900 and 1200 lbs). Dugongs are often less than 3 m (8–10 ft) in length with an average weight of 420 kg (510–1100 lbs). Females are usually larger than males (Odell 1982).

They are primarily warm water inhabitants and can become ill or die in cold water. When water temperatures get colder, they seek out warm waters and have been found crowding around the output of warm outflows of electric power plants and paper mills (Bossart et al. 2002). This sensitivity to cold water is likely due to their low metabolic rate.

## Digestive System

Sirenids have large flexible bristled prehensile lips. The upper lip contains shortened sensitive sensory vibrissae, which allow for accurate food detection. The flexible lips are used to manipulate and gather food into its mouth. Dugongs and manatees differ in the fact that dugongs have a longer more “trunk-like” mouth with incisors or tusks, which are not present in manatees. These tusks can be seen projecting from the lips primarily in older male animals. Manatees have shifting similarly shaped molars that move forward as they wear out from grinding their teeth when chewing their food. Dugongs have six finite-fixed premolars and molars (Domning and Beatty 2007). Uniquely, the open-rooted two rear molars continue to grow throughout the life of the animal.

The digestive tract is extensive and reflective of its herbivorous diet requiring unique adaptations to metabolize and absorb food for nutrition. The simple stomach with its digestive cardiac gland helps breakdown complex plant cellulose and the extensive hindgut, similar to horses, are examples of adaptations producing one of the highest digestive coefficients (cellulose 80%) of any known herbivorous mammal (Burn 1986).

Manatees can often be seen seeking out fresh water sources.

## Special Senses

The eyes are well developed and have fairly good visual acuity (Hartman 1979). The eyelids open and close in a circular fashion similar to a camera lens and they have a nictitating membrane that protects and covers the eye when needed. Hearing is very acute and the ears are completely internal. They have large ear bones, which can also be used for aging (Marmontel et al. 1996). They emit various sounds used to communicate with each other during sexual, and play encounters but is distinctly used between mother and calf.

## Relationship of Lungs, Blood, and Bone Density

The dorsally placed nares quickly opens when the animal surfaces and deeply inhales. It then closes when swimming or diving. Air travels into the lungs where approximately 90% air exchange occurs in comparison to approximately 10–20% in humans (Rommel and Reynolds 2000).

The long bones of manatees and dugongs are solid and do not have a marrow space used to produce blood cells as in many terrestrial animals. Blood cells are primarily made from marrow found in the sternum. The heavy bone structure creates a negative buoyancy making their bodies sink in water, thus they have large elongated lungs placed dorsally along their backs to help compensate creating positive buoyancy (Rommel and Reynolds 2000).

## Pectoral Fins

The two pectoral fins or forelimbs are elongated, jointed, and paddle shaped. Their uses include steering, maneuvering, touching, and placing food into their mouth. Two manatee species have three to four nails, while dugongs and the Amazonian manatee do not.

## Morphological Adaptations and Survivability

The evolutionary adaptations found in manatees have unfortunately made them sensitive to numerous environmental and manmade dangers, which threaten their survival.

In the United States and Caribbean along coastlines and rivers, manatees are hit by fast-moving boats or jet skis when surfacing to breathe. These unfortunate impacts can be life-threatening as propellers tear through their backs where the elongated lungs are located. Infections, free air in the thorax (pneumothorax), and damage to bones are all sequelae to this constant danger. Deep cuts can also cause damage to the paddled fluke, which disrupts the animal's ability to swim. Because the animals are gray in color and their nares barely break the surface to breathe, they often blend in with surrounding waters and are difficult to see by water vehicles traveling at high speeds. Jet skis, for example, can cause significant trauma to the skull on impact to these slow-moving animals.

Another threat to their survival is monofilament fishing lines, nets, and numerous forms of discarded plastic left in water by humans. Entanglement in these lines can cause severe damage to the pectoral fins cutting off circulation and causing loss of the entire limb or even drowning.

Floodgate crushing injuries around power plants associated with the animals seeking warm water is also a perilous issue.

## Conclusion

The anatomy of all mammals is similar with adaptations often defined by evolutionary pressures placed on the species. Sirenian adaptations have evolved to produce the only herbivorous marine mammal known to exist today. Their specialized diet has produced an oral cavity adapted for their food resources. Their body structure and mobility in water are defined by their skeletal and muscular anatomy and appendages. Their buoyancy is defined by the weight of their skin, long bone structure, and pulmonary tissue. Their long

gestation period of approximately 1 year and milk-producing mammary glands are highly specialized for calf survival. All of their reproductive organs are located internally.

The majority of each adaptation has a specialized function and provides insight into the life history of the animal. In today's world of animals constantly being threatened with extinction, an understanding of these morphological structures is beneficial in understanding why these animals have been threatened with extinction. It will also likely prevent them from following in the same path of their extinct counterparts, the Steller's sea cow.

## Definition

The behaviors of members of order Sirenia that allow them to interpret, move, and survive in their environment.

## Introduction

Species in order Sirenia are the only fully aquatic, herbivorous marine mammals. This order is comprised of sea cows, the extant species being the dugong (*Dugong dugon*) and three species of manatee (genus *Trichechus*). All species of dugongs and manatees are currently listed as vulnerable with a declining population trend. Sirenia inhabit coastal wetlands, coastal marine waters, rivers, freshwater lakes, and estuaries. They feed on sea grass and other bottom-dwelling marine vegetation. These sea creatures navigate throughout their home ranges to find food, seek mates, and escape predators. Species in temperate climates migrate long distances towards warm waters during winter.

Navigation is the capability of assessing position and being able to move in a specific route

based on that position. Many animals use navigation in multiple forms to aid survival. For example, some bat species use echolocation or biosonar (i.e., reflection of high-frequency sound waves) to navigate towards their prey; whereas wildebeests (*Connochaetes* spp.) use olfaction to navigate during their annual migration. Manatees and dugongs use a combination of morphological adaptations, memory, and environmental cues to navigate. Improving our understanding of Sirenia navigation could aid conservation efforts to restore these imperiled species.

### Morphological Adaptations for Navigation

Order Sirenia has several morphological adaptations related to navigation. Fully aquatic mammals, like manatees and dugongs, have either reduced or absent olfactory organs, so they must rely on other appendages and features to locate food. Sirenia have evolved vibrissae as a replacement for olfactory organs. Vibrissae are tactile sensory organs used to navigate the environment. Sirenia have several vibrissae, or bristles, mainly located on the snout. The West Indian manatee (*T. manatus*) has thousands of vibrissae covering its entire body (Marriott et al. 2013). Facial bristles are used for tactile foraging and raking vegetation into the mouth (Marriott et al. 2013). Muscles in the face are an essential part of bristle movement and effective foraging maneuvers, such as raking plants into the mouth (Marshall et al. 1998). Marshall et al. (1998) classifies the manatee vibrissal-muscular system as a muscular hydrostat – a muscular structure that allows for complex movement, sophisticated coordination, and directional change support. Manatees can also use the left and right clusters of vibrissae independently for even more controlled movements (Marshall et al. 1998). Dugongs have displayed a behavior in which they move their head up and down, allowing their vibrissae to skim over the surface of an object (Marshall et al. 2003). This behavior is interpreted as exploratory, perhaps feeling for texture or object recognition (Marshall et al.

2003; Reep et al. 2011). Reep et al. (2011) compares the manatee's oral disk vibrissae to the function of an elephant's trunk. Dugongs have also exhibited cleaning behavior, performing facial motions, such as wrinkling their snouts, or using their flippers in attempt to rid facial bristles of plant debris (Marshall et al. 2003). It is thought that these animals clean their bristles in order to keep sensory pathways open to receive accurate navigational information or to allow for full range of movement of the bristles (Marshall et al. 2003).

Post-facial bristles are dedicated to translating hydrological information through passive detection such as tide shifts, temperature changes, and sensing vibrations (Reep et al. 2011). One study estimates that vibrissae have sensitivity similar to that of a fish's lateral line or a human index finger, if not greater (Reep et al. 2011). Observation of West Indian manatees shows careful and constant movements of their flukes when navigating through the water, presumably because this area of the body is a highly important part of receiving sensory feedback (Sarko et al. 2007). Vibrissae are also sensitive to low-frequency sounds, which help manatees navigate toward objects and the source of the stimuli, similar to how a bat's echolocation waves reflect off of prey (Sarko et al. 2007). It is estimated that Sirenia can detect sounds from 5 to 150 Hz (Reep et al. 2011).

While vibrissae are common adaptations throughout all of Sirenia, the angle of the snout can indicate navigational habits between different species. Snout angle determines at which trophic level Sirenia species feed. Manatee species' snout angles vary between 26° and 38°, and the more downturned the snout, the greater depth in the water column the species feeds (Marshall et al. 2003). Species with a only slightly downturned snout, like West African (*T. senegalensis*) and Amazonian manatees (*T. inunguis*), are adapted to feed primarily on floating vegetation, while snouts with a great angle, like West Indian manatees, can feed on both floating and mid-water vegetation (Marshall et al. 2003). In contrast, dugong snouts are downturned by approximately 70°, adapting it to feed mainly on benthic vegetation (Marshall et al. 2003).

## Home Range

Sirenia home ranges are typically divided into two sections by season – winter home ranges and summer home ranges (Holley 2006; Arraut et al. 2009). Sea grass cover of at least 30%, water temperature, and shallow water depth are determining factors for choosing a home range (Holley 2006). Water salinity also dictates home range depending on the species, and as that water composition shifts, so will the home ranges of Sirenia. For example, West African and West Indian manatees can withstand salinity levels ranging from saline (i.e., marine) to freshwater, whereas the Amazonian manatee only inhabits freshwater rivers, lakes, and floodplains (Marshall et al. 2003). Summer and winter home ranges include the cumulative of locations each individual visits and areas of travel between locations. One study found that the mean home range size for dugongs vary from 4.1 km<sup>2</sup> to as large as 43.4 km<sup>2</sup> (Longh et al. 1998). Individual home ranges can overlap, and many studies suggest Sirenia will exhibit conspecific social interactions. Although Sirenia are known to congregate in warm-water foraging areas, each animal exhibits independent movement patterns and demonstrates variation in daily distance travelled or locations visited (Longh et al. 1998). Overlapping movements of individuals may indicate seasonal herding behavior, yet Sirenia still exhibit highly individualistic movement patterns (Holley 2006).

Sirenia are slow-moving creatures, often traveling well under 1 km per hour (Longh et al. 1998; Holley 2006). However, Sirenia can still cover significant distances outside of migration season. One study that followed tagged dugongs observed them traveling on average between 3 and 23 km per day (Holley 2006). Brief non-migratory excursions, dubbed “exploratory movements,” can also occur during which an individual may deviate from its typical range for a few days before returning to its normal home range (Holley 2006).

Vertical movement, specifically diving, has not evolved as a strong behavioral adaptation in these marine mammals. While Sirenia are capable of making small dives for benthic vegetation, deep

diving has not been selected for as a foraging behavior due to their preference for the shallower water benthic communities in which sea grasses grow (Sheppard 2008). However, significant dives of approximately 40 m deep have been recorded in dugongs, implying that these animals will make dives when necessary for foraging (Sheppard 2008). Dugongs move laterally with the tide, traveling closer to shore by night, perhaps because they are using tides as environmental cues to navigate towards vegetation or avoid predation in deeper waters overnight (Sheppard 2008). Dugongs also respond more to daily tidal patterns than do manatees, perhaps because manatees, unlike dugongs, can utilize freshwater habitats with little or no tidal activity (Sheppard 2008).

## Migration

Little is actually known about Sirenia migration or the mechanisms that drive it. A majority of migration data is gathered through radio telemetry. This method of data collection presents a problem when studying navigation because of limited signal transmission capacity underwater; therefore, there may be bias towards the mapping of foraging and resting areas while the migration corridors and pathways are underrepresented (Flamm et al. 2005). Manatees and dugongs migrate south between October and November when the water is colder and water levels are low, returning north in the spring (Arraut et al. 2009). Sirenia species have also been shown to migrate following a flood-pulse system, as varying water levels allow connectivity between locations. Sirenia prefer to move closely to shorelines rather than open water (Flamm et al. 2005). Manatees migrate at a constant rate by day and by night with males typically moving faster than females (Arraut et al. 2009; Flamm et al. 2005). Because of the lack of empirical data, much guesswork is done about the mechanisms that drive Sirenia migration. However, environmental cues such as water temperature and visual landmarks seem to be the main mechanical components of navigation.

Similar to home range movements, migratory behaviors and routes vary greatly between individuals. Flamm et al. (2005) suggests these differences indicate that navigation is choice-motivated by each individual, influenced by previous migration experience. In contrast to behavior within the home range, dugongs have been recorded to make frequent deep dives while migrating (Sheppard 2008). Two hypotheses have been proposed for this behavior: (1) dugongs make deep dives to avoid predation by sharks, (2) dugongs swim along the ocean floor to reduce the energy needed to swim against currents and drag in the open water (Sheppard 2008). More experimental research is needed to test these hypotheses.

Migration destinations are divided into two types: habitats and refuges (Sheppard 2008). Habitats are generally where the water is warm and sea grass is abundant; refuges are where there is a warm water hotspot, either naturally occurring or anthropogenically influenced. Sea grass is typically in proximity to warm water refuges – close enough to support daily foraging visits (Sheppard 2008). Despite the overwintering destination, migration in most Sirenia species still occurs to maximize optimal foraging activity throughout each season. Interestingly, migratory choices by Amazonian manatee present an exception to this concept. This tropical species migrates to waters where it spends months without an abundant supply of food (Arraut et al. 2009). It is hypothesized that this behavior occurs to avoid caimans and jaguars that can easily hunt them in low waters (Arraut et al. 2009). Differences between migration behaviors within Sirenia may be due to regional environmental variability (e.g., water temperature, seasonally varying forage availability, and predator context) and/or inherited migratory programs reflecting evolutionary history of manatees that drive some species to travel further north compared to their migratory tropical counterparts.

## Brain, Memory, and Navigation

Although little research has been conducted on the subject, Sirenia use a sophisticated

somatosensation system to navigate (Marriott et al. 2013). Somatosensation is a complex system of sensory neurons that responds to changes in and outside of the body. These neurons send signals directly to the central nervous system. Sirenia somatosensation acts through the vibrissae (see above), which are highly nerved (Sarko et al. 2007). Vibrissae are sensitive to thermal changes in the environment and water flow (Marriott et al. 2013). The central nervous system receives and interprets information from vibrissae on the oral disk, mouth, flippers, and fluke (Reep et al. 2011). Somatosensation works in conjunction with color vision to navigate the underwater environment. Studies find through brain examination that the nuclei associated with somatosensation are many times larger than the nuclei of any other sensory input (Sarko et al. 2007; Marriot et al. 2013). The somatosensory input mechanism of the thalamus is also much larger by volume than any other section of the thalamus (Reep et al. 2011).

In addition to somatosensation, Sirenia develop cognitive, or mental, maps over the course of their lifetimes to aid in navigation. As mentioned briefly above, it is hypothesized that navigation is partly choice-motivated. Flamm et al. (2005) suggests that experienced manatees make navigational choices based on the memory each animal has about its environment and previous experiences, while inexperienced individuals are “geographically naïve” (p. 1423) and rely more heavily on environmental cues and somatosensation to guide them. Development of a mental map is key to survival in both the home range and during migration. Sirenia appear to memorize areas of high-quality food locations within their home ranges (Sheppard 2008). It stands to reason that older dugongs with a more developed mental map would forage more efficiently than younger dugongs and calves. Dugongs and manatees have also been recorded avoiding established seagrass beds during migration, perhaps to avoid territorial encounters with other individuals (Sheppard 2008). Memory development seems to come from both environmental and tactile experiences. Sirenia are able to recognize specific objects due to the sophisticated neural cells that

are activated through use of vibrissae (Sarko et al. 2007). Further research is needed on how vision and somatosensation works in conjunction with memory to develop navigation behavior.

### Abiotic and Biotic Factors that Influence Navigation

The largest abiotic threat to Sirenia is climate change. Climate change causes more frequent droughts in the Amazon, causing migration pathways of the Amazonian manatee to be disconnected by the lower water levels and stranding individuals in unsuitable patches during drought migration (Arraut et al. 2009). A similar situation occurs in Florida where natural warm water springs grow shallower, slower, more saline, and more polluted resulting in manatees being unable to access and utilize the springs during critical overwintering periods (Edwards 2013). The Florida manatee (*T. manatus latirostris*) may also be impacted by the increased frequency and severity of storm events along the Gulf of Mexico coast, causing some groups to vacate historic migration sites and relocate to different areas (Langtimm et al. 2006; Edwards 2013). Severe storms also disrupt sea grass communities, often submerging plants under substrate or redistributing plants to other areas, which can lead to starvation in migratory manatees and dugongs (Edwards 2013). Hurricanes also cause manatees to die from the shock of cold waters that come after hurricanes (Langtimm et al. 2006). Cold water dulls the sensing capabilities of the vibrissae, thus reducing or muddling the information being received through these organs necessary for navigation (Langtimm et al. 2006). Storms also generate strong water currents that could push manatees and dugongs off their intended course or sweep them out to deep sea (Langtimm et al. 2006). Otherwise, data shows that these marine mammals prefer to stay where they are and ride out the storm (Langtimm et al. 2006).

Another effect of climate change is an increase in the amount and potency of toxic red tide algal blooms (Edwards 2013). The toxin of red tides,

known as Brevetoxin, is inhaled or absorbed through the skin and disrupts nervous system function through a form of neurological poisoning. This results in lethargic or comatose animals, which quickly leads to mortality. As oceans warm, algal blooms may appear earlier, persist longer throughout the season, and possibly expand in geographic range. Sirenia, especially the Florida manatee, now have to migrate through these waters with early-arriving blooms. In 2013, an estimated 643 manatees were shown to have died from exposure to red-tide algal blooms with an estimated exponential increase of death in subsequent years (Edwards 2013).

Overall, the system of Sirenia navigation has adapted to accommodate rapid environmental alterations caused by climate change, yet these adaptations are mainly favorable for summer conditions. Sirenia in North America appear to be expanding their summer range northward, traveling farther up along the Atlantic coasts than ever before (Flamm et al. 2005; Edwards 2013). One study notes that manatees have now been spotted in Massachusetts (Edwards 2013). However, these abiotic factors are wreaking havoc on southern ranges and winter migratory behavior. This has resulted in an inability to complete winter migration to the proper habitat, high mortality rate during winter migration, and altered or insufficient overwintering habitats upon arrival.

In addition to drought, hurricanes, and red tide, anthropogenic alterations have also impacted Sirenia navigation. Manatees and dugongs prefer warm waters and migrate to warmer places for the winter. Power plants warm the surrounding waters, and manatees have increasingly chosen these industrial water sites as winter refuges over natural sea grass habitats (Edwards 2013). If these power plants ever cease operations, aggregating manatees in these areas are at high risk for mass mortality events, an example of an anthropogenically induced ecological trap (Flamm et al. 2005). Several studies conclude that manatees show strong site fidelity. It is hypothesized that manatees will not migrate to a different area even when the water temperature decreases below critical thresholds and renders the habitat unsuitable

(Edwards 2013). Migrating to these industrial sites also increases the chance of watercraft collisions in areas with greater boat traffic (Edwards 2013).

## Conclusion

There are many aspects to consider when studying Sirenia navigation. Evolution of morphological features has developed mechanisms that allow Sirenia to navigate their environments. These mechanisms can be studied through observing and experimenting with behaviors as Sirenia navigate and interact with their environment. Tactile interactions and life experience lead to the formation of mental maps and memories. These important brain functions aid with foraging and migration patterns, both of which increase survivability. Like so many other species today, climate change and human activities have greatly impacted Sirenia and may be driving selection pressures to develop certain navigational behaviors. Many of these factors work together and combine functions to form the big picture of Sirenia navigation. Much more research and documentation is needed to fully understand Sirenia navigation – especially topics of neurological functions, facultative herding behavior, and the mechanisms that drive migration – and improve efforts to conserve the remaining species.

### Introduction

Manatees (*Trichechus*) and dugongs (*Dugong dugon*) comprise the four extant species in the Order Sirenia. Their closest terrestrial relatives include elephants and hyraxes. Sirenians inhabit shallow coastal areas and river systems. West Indian (*Trichechus manatus*) and West African manatees (*Trichechus senegalensis*) are euryhaline; Amazonian manatees (*Trichechus inunguis*) inhabit rivers and lakes; and dugongs are exclusively marine (Marsh et al. 2011). Most behavioral studies of captive sirenians have only been initiated within the last two to three decades with little opportunity for replication; therefore, most findings are based on single studies. Experimental behavioral research on sirenian senses has been done primarily with West Indian manatees. Few sensory reports are published on the other manatee species or dugongs, consequently, unless otherwise stated, “manatee” will refer to studies of the West Indian species.

The behavioral-perceptual world of any animal is largely determined by the range of external stimuli that it can detect and the range of movements that it is capable of making. These traits co-evolve strongly with feeding and mating strategies and are also related to modes of communication and to energetic needs. Available anatomical and behavioral evidence suggests that manatees are somatosensory specialists,

with excellent hearing, reduced vision, and modest olfaction and taste. Manatees are mostly solitary, obligate aquatic herbivores that spend several hours per day engaged in feeding behavior. Groups appear to be temporary, based on resource concentrations (Marsh et al. 2011). In Florida, they navigate intricate coastal estuarine environments, with few visual cues to locate desired feeding areas. Their social behavior involves primarily cow-calf interactions. Mating takes the form of scramble polygyny, in which several males follow a female for days to weeks and engage in serial mating. Large winter aggregations of manatees occur at warm water sites due to thermoregulatory needs. Manatees have a low metabolic rate, which is associated with large body size and aquatic herbivory (Reep and Bonde 2006).

Compared to other mammals, manatees have small brain size in relation to their body size, but it is likely that selection pressures related to aquatic herbivory have resulted in large body size due to the need for an expanded gut. Thus, the brain may not be small relative to the body; rather, the body is enlarged relative to the brain (O’Shea and Reep 1990).

## Sensory Processes of Manatees

### Somatic Sensation

The hairs on manatees constitute a major source of somatosensory input to the central nervous system. All of the hairs are sensory hairs (vibrissae), defined anatomically as having a circumferential blood sinus, dense connective tissue capsule, and a variety of innervated mechanoreceptors (Sarko et al. 2007). This is in contrast to other mammals, in which sensory hairs are confined to restricted body regions, mostly on the head (Hyraxes are a notable exception, having both pelage hair and sensory hairs on the entire body.). Manatee sensory hairs move in response to water displacement or direct contact with objects including plants, conspecifics, and features in the environment. When a sensory hair is deflected, it makes contact with the follicle wall that contains mechanoreceptors. These receptors transduce mechanical energy

into electrical signals that are transmitted via axons to the brain.

There are three major categories of vibrissae on manatees based upon location, microscopic anatomy, and functional role: perioral bristles used in prehensile grasping, bristle-like hairs of the oral disk used in active tactile scanning and passive detection of water movements, and postfacial vibrissae, which passively detect water movements. Vibrissae are 30x denser on the face than on the postfacial body, reflecting the specialized anatomy and function of the facial region (Reep et al. 2011). Manatee tactile investigation often involves tactile scanning by the bristle-like hairs of the oral disk, followed by oripulation (Marshall et al. 1998; Bauer et al. 2012). Tactile scanning begins with eversion of the bristle-like hairs, and then continues with side to side movements of the head that allow the array of ~600 vibrissae of the oral disk to explore the object of interest. In some situations, tactile investigation also involves active poking movements of the perioral bristles. Feeding behavior and tactile investigation of objects, such as anchor lines, engage the perioral bristles in oripulation, grasping movements that are mediated by facial muscles innervated by the brainstem facial motor nucleus, which is large and exhibits discrete subnuclei.

Each manatee vibrissa emerges from a follicle-sinus complex (FSC) that contains hundreds of mechanoreceptors of at least three of the following types: Merkel, club, lanceolate, lobulated, tangle, trabecular, and free nerve endings. These follicles receive extensive innervation by C, A $\delta$ , and A $\beta$  axons (Sarko et al. 2007). The head region contains ~2000 vibrissae, and each FSC is innervated by 50–250 axons, resulting in a subtotal of ~109,000 myelinated axons supplying the FSCs of the head region. The postfacial body contains ~3300 vibrissae, with each FSC innervated by ~30 myelinated axons, for a subtotal of ~100,000. Thus, on the entire body of a manatee there is a total of ~5300 vibrissae and FSCs innervated by ~209,000 myelinated axons. Innervation of the head region vibrissae is via the trigeminal nerve; innervation of the postfacial body is via spinal afferents.

The large amount of information related to sensory hairs is conveyed by over 200,000 axons to several large, lobulated somatosensory nuclei in the brainstem. Axons from the face and head terminate in the trigeminal nuclei. Axons from the forelimb flipper and trunk reach the cuneate-gracile complex. A prominent Bischoff's nucleus, present in many tailed mammals, is also found in the caudal brainstem of manatees, suggesting that sensory input from the fluke is important. This is consistent with the multitude of adjustments made in the position of the fluke during swimming. The thalamic nuclei that receive input from the somatosensory brainstem nuclei are large relative to the nuclei related to other sensory modalities. The putative somatosensory cerebral cortex is likewise large and subdivided into several distinct areas. Neuronal aggregations known as Rindenkerne ("cortical nuclei") are found in the deep layers of some of these cortical areas. The Rindenkerne are hypothesized to process information from individual hairs, similar to the cortical barrels found in other mammals with vibrissae (Reep et al. 2011).

The rich neural elaboration of the somatosensory system is reflected in tactile sensation. In psychophysical experiments of manatee passive touch (mechanoreception), subjects stationed in the presence of a sinusoidally oscillating sphere, which generated a dipole, hydrodynamic stimulus. Using a go/no-go procedure with a staircase method, two manatees detected particle displacement of less than a micron at frequencies between 15 and 150 Hz and as low as a nanometer at 150 Hz (Gaspard et al. 2013, 2017). Thresholds were about one order of magnitude higher on the postcranial body than on the face. Elevated thresholds found after restricting facial vibrissae with a mesh mask and also after shaving an area of the torso indicated that the vibrissae provide increased tactile sensitivity. Manatees' remarkable ability to detect small water movements makes it probable that they can discriminate objects that divert water flow in subtle ways, as well as track major currents.

In tests of active touch (haptic reception) manatees discriminated small differences in grating widths in a two alternative, forced-choice

procedures (Bachteler and Dehnhardt 1999; Bauer et al. 2012). The manatees had interpolated discrimination thresholds between 2.05 and 2.15 mm when tested against a 2 mm standard. These differences can also be expressed as Weber fractions (just-noticeable-differences) of  $k = 0.025$  and  $0.075$ , where  $k$  is a constant determined by the ratio of the smallest detectable magnitude change divided by the magnitude of a standard stimulus. The manatee's ability to discriminate fine gratings using active touch suggests they can tactually resolve small details of objects in their environment.

### Audition

Manatees have short vocalizations (~400 ms) consisting of fundamental frequencies and harmonics ranging between about 3 and 20 kHz (Reep and Bonde 2006) as well as broadband components. There is no external ear, merely a small opening to the auditory meatus (Supin et al. 2001; Wartzok and Ketten 1999). The ossicular chain is massive. The cochlea has a typical mammalian spiral design. The basilar membrane, however, shows little base-to-apex differentiation in width. An airspace, the hypotympanic recess surrounding the cochlear capsule, may isolate the ear from the cranium, an important adaptation for sound localization (Chapla et al. 2007). The auditory/vestibular nerve (cranial nerve VIII) is a prominent feature of the lateral brainstem. Brainstem nuclei dedicated to hearing exhibit good differentiation, and include an enlarged nucleus of the lateral lemniscus (interestingly, this feature is also seen in echolocating bats and cetaceans, though there is no evidence for echolocation in manatees). The caudal colliculus of the midbrain is robust in size, and the medial geniculate nucleus of the thalamus is very large relative to other thalamic nuclei, as are the putative auditory cortical areas.

Hearing by manatees has been investigated using a variety of techniques. Their audiogram, the array of detection thresholds for the range of frequencies within their hearing range, was behaviorally determined using go/no-go (Gaspard et al. 2012) and two alternative choice procedures (Gerstein et al. 1999) in conjunction

with a psychophysical staircase method. Manatees could detect tonal sounds across a wide range of frequencies, as high as 76 kHz, greater than two octaves higher than a human adult, and as low as 250–400 Hz. An evoked potential study of an Amazonian manatee revealed sensitivity to a similar frequency range, 5–60 kHz (Supin et al. 2001). The narrower frequency range reported for this species may merely reflect the relative insensitivity of evoked potential techniques for manatees.

Critical ratios, estimates of the ability to hear in noise measured as the decibel difference between the tonal signal and background sound, indicated that manatees were able to hear well in noise with values ranging from 18.3 to 34.1 dB for tonal frequencies from 4 to 32 kHz (Gaspard et al. 2012). This sensitivity is especially strong in the range of the second and third harmonics of the tonal components of typical manatee vocalizations (fundamental ~4 kHz). Manatees may utilize the more variable upper harmonics to detect differences between calls, thus allowing identification of individuals. This is consistent with the observed peak hearing sensitivity at 8–32 kHz (Gaspard et al. 2012; Gerstein et al. 1999). The broadband aspects of phonations (O'Shea and Poche 2006) would also make them more localizable.

The auditory temporal processing rate of manatees, measured as the ability of the nervous system to map amplitude modulated tones, was determined using an envelope-following, evoked potential technique. Neural response measurements made in the thick dermal layer of the cranium indicated that subjects had high auditory temporal processing rates, up to 600 Hz (Mann et al. 2005). Later behavioral studies indicated that they could localize broadband sounds well in the azimuth plane (Colbert-Luke et al. 2015; Bauer et al. 2010), perhaps an adaptation for navigation in natural conditions where they might be able to localize surf or moving bodies of water through auditory scene analysis. Head (Body)-related transfer functions (HRTF) indicated that the manatee's large bodies shadowed sounds providing a potential sound localization cue.

Dugongs produce a variety of phonations in a similar range to manatees (3–18 kHz), although the length of these vocalizations may be considerably longer, over 2 sec in the case of trills (Anderson and Barclay 1995). Although no psychophysical testing of dugong hearing has been reported, it is usually safe to say that mammals are able to hear in their vocalization range.

## Vision

Manatees have small eyes in relation to body size and correspondingly small extraocular eye muscles. Unlike cetaceans and pinnipeds, which have spherical lenses, manatees have lenticular lenses, wider in the axial dimension than the transverse (Supin et al. 2001). There is a relatively low density of retinal ganglion cells, which is an anatomical indicator of visual acuity in many mammalian species. The optic nerves are very small, as are the lateral geniculate nuclei of the thalamus, a major center subserving form vision, in which many axons of the optic nerve terminate. The putative visual cortex is modest in extent. The rostral colliculi are modest in size; these receive other inputs in addition to those from the retina.

Visual acuity estimated from ganglion cell density in conjunction with the distance from the center of the lens to the retina is 20 arc minutes. Subsequent psychophysical tests using a method of constant stimuli in a two alternative forced-choice paradigm determined that the minimum angle of resolution (MAR) for one manatee was 21 arc minutes for horizontal gratings and 23 min for vertical gratings measured at one meter, closely in agreement with the estimate from anatomy. A lack of improvement when this manatee was tested at a closer distance suggests that manatees are emmetropic (no refractive error, image falls on the retina) or hyperopic (farsighted, image falls behind of the retina) underwater, consistent with the conclusion of Piggins et al. (1983) based on anatomical data of an Amazonian manatee. Further support for emmetropia/hyperopia was provided by a preliminary analysis of refraction using streak retinoscopy suggesting that a tested manatee was emmetropic-to-hyperopic

both underwater and in-air. The possibility of emmetropic vision both in-air and underwater would be an unusual combination, since the involvement of the cornea as a major refractive element in air coupled with its refractive neutrality underwater should typically lead toward specialization for only one of the environments, but not both. Notable exceptions are marine mammals, where dolphins and sea lions have developed specialized adaptations for focused vision in both environments (Wartzok and Ketten 1999). Follow-up behavioral and ophthalmological work with manatees is indicated to determine if the Sirenia constitute a third group of marine mammals with adaptations for both in air and underwater vision.

Manatees have modest brightness discrimination with Weber fractions ( $k = 0.35$ ) similar to fur seals (0.34) but higher than humans ( $k = 0.11$ ) (Griebel and Schmid 1997), indicating less sensitivity than humans. Different methods were used to assess brightness discrimination among these species, so comparisons are tentative.

Unlike other marine mammals such as the pinnipeds and cetaceans, which are monochromats, manatees are dichromats with short-wave and long-wave length receptors (Ahnelt and Kolb 2000; Marsh et al. 2011) more typical of terrestrial mammals. Psychophysical evidence supports the anatomical evidence indicating that manatees have dichromatic color vision in the blue and green range (Griebel and Schmid 1996). Their relatively modest visual acuity in conjunction with dichromatic color vision suggests an eye adapted for intermediate to long distance viewing appropriate for seeing patches of plants.

## Chemoreception

Manatees have reduced olfactory epithelium and olfactory bulbs, as is the case for other fully aquatic mammals. Likewise, the central olfactory nuclei and olfactory cortex are very modest in extent. Manatees also lack a vomeronasal organ, which functions in the detection and identification of pheromonal stimuli in many terrestrial mammals. Taste buds are present on the tongue and soft

palate in manatees but are rather restricted in number and distribution in comparison with many other mammals (Marsh et al. 2011; Reep and Bonde 2006). These findings appear to suggest a reduced role for chemosensation, but the finding of anal glands in manatees (Bills et al. 2012) and naturalistic observations suggest that there is much to learn about manatee chemosensation.

Manatees have been reported to use particular rubbing posts (Hartman 1979; Wells et al. 1999), an activity that especially makes sense if the posts retain chemical information regarding previous users of the posts. Manatees in social settings mouth one another (Hartman 1979) again suggesting that chemical cues may carry information regarding individual identity, sexual status, or other parameters. Manatees consume other manatees' feces, perhaps an example of coprophagy (Reynolds and Rommel 1996) as exhibited by a number of hindgut digesters, but also, perhaps to obtain information about reproductive status or dominance. In addition, various scientists have noted that mating herds of manatees form when roving males encounter and accompany estrous females for periods of several days. It is very possible that estrogen or other chemical cues from females in estrus are detected by the males and facilitate mating herd formation (Reynolds and Odell 1991). Thus, chemoreception may play a role in social and reproductive behavior of manatees.

Chemoreception in sirenians has not been studied with psychophysical methods in a rigorous laboratory environment. It may play an important role in social and reproductive behavior and in selection of appropriate habitat. Manatees show certain habitat preferences that can be extremely specific. Acoustic and tactile cues may provide part of the answer, but chemical reception may also play an important role.

## Conclusion

Some senses used by other aquatic mammals are apparently lacking or diminished in manatees. They do not echolocate, they have modest visual

acuity, and neuroanatomy suggests unimpressive chemical senses. Excellent hearing across a wide range of frequencies and good sound localization ability may provide a means for auditory scene analysis, but this is speculative. Alternatively, the tactile senses may provide a rich platform for detailed analysis of the environment. The available evidence suggests that manatees utilize the vibrissae distributed over the body as a three dimensional array to detect and localize hydrodynamic stimuli, a likely source of information important for orientation and navigation. These stimuli would be useful for detecting conspecifics, water currents, tidal flows, and objects in the environment. This conception is similar to the concept of the lateral line system of fish and amphibians as mediating "touch at a distance." The facial vibrissae are also utilized in direct contact, during tactile scanning and oripulation.

Hydrodynamic reception appears to be of general ecological value, as evidenced by the presence of this capability throughout animal taxa. Elongated hairs or hair-like appendages associated with mechanoreceptors that respond to hydrodynamic stimuli are found in a wide variety of invertebrate and vertebrate taxa (Bleckmann, 1994).

**Size Constancy, Fig. 1** Experimental setup for Holway and Boring (1941) size constancy study

## Situated Cognition

### ► Embodied Cognition

## Size Constancy

Rachel T. Walker  
Department of Psychology, University of the  
Incarnate Word, San Antonio, TX, USA

Size constancy occurs when the perception of an object's size remains constant, despite the relative distance from the observer (McKee and Smallman 1998). It allows us to understand that the size of a nearby object is the same size of an object that is further away. This explains how a retinal image can change, because of varying distances, but the perceived size of the object remains unchanged.

### History: Holway and Boring (1941)

In a classic study, Holway and Boring (1941) considered the potential role of depth cues on size constancy. The participants in this study were shown discs within two different corridors. One corridor provided a test disc (i.e., sample), and the other corridor provided a comparison disc that the participant could manipulate. During the experiment, the size and distance (i.e., depth cues) of a test disc were modified by the researchers

(Fig. 1). Researchers also manipulated the visual perception of the participants: binocular vision, monocular vision, and impaired vision (e.g., viewing discs through a small hole to decreased additional depth cues). On each trial, participants were asked to match the size of a test disc by manipulating a comparison disc to the perceived size of the sample.

Holway and Boring (1941) found that when all depth cues were available, observers were more accurate in perceiving size constancy than when some of the cues are missing or displaced. These distance cues play a critical role in not only perceiving depth but also maintaining size constancy.

### Underlying Factors of Size Constancy

The usefulness of visual cues creates an individual's perception of the world, such as depth perception. Depth perception is the ability to judge the distance and spatial relationship between objects. The visual cues are detected by both binocular and monocular vision. Binocular vision is the ability to perceive three-dimensional space as a result of two eyes working simultaneously to integrate binocular cues such as binocular disparity (i.e., the difference in where the image is located on the back of each eye) and convergence (i.e., when both eyes move together to look at a nearby object). Monocular vision, on the other hand, involves the use of one eye to gather information from the

environment. Monocular cues arise from the way a three-dimensional world is projected onto a two-dimensional retina (e.g., aerial perspective, linear perspective, relative size). Relative size, the use of familiar objects to judge size without depth, is related to size constancy. Despite these relatively standardized processes used to determine size constancy, there are times when visual perception can be misleading and visual illusions can occur. One example of a visual illusion, that is related to size constancy, is the Ponzo illusion. This illusion helps us understand how we process linear perspectives. We perceive the image of a horizontal line to be longer when it is moved farther away from us, while in fact the length of the line has not changed.

### Size Constancy in Animals

Size constancy has also been studied in a diverse group of species. Some species, such as insects and fish, rely on visual cues to determine their distance from an object. For example, the praying mantis uses side-to-side head movements in a horizontal plane to determine the jump distance to stationary objects and appears to use size constancy in depth judgments (Maldonado and Rodriguez 1972). For this species, it seems that the fixed compound eyes and head movement increase accuracy in distance information. In another study, Douglas et al. (1988) examined the ability of goldfish to discriminate between two circular discs of different sizes. The goldfish was trained to select one of the discs, termed the target disc. Once the discrimination was learned the discs were placed at various distances and the goldfish was required to select the target disc. The goldfish continued to select the target disc regardless of the distance which supported their use of size constancy. While most of the research has focused on animal and human vision, it should be noted that other senses have been studied. In a unique study on a blind individual that used echo clicks, researchers found that their sensation of sound also could be related to size constancy (Milne et al. 2014).

### Size Illusion

Audrey E. Parrish<sup>1</sup> and Michael J. Beran<sup>2</sup>

<sup>1</sup>Department of Psychology, The Citadel, Charleston, SC, USA

<sup>2</sup>Department of Psychology and Language Research Center, Georgia State University, Atlanta, GA, USA

A variety of geometric illusions that are experienced by humans lead to errors in size estimation of stimuli. Some of these illusions have been studied from a comparative perspective. These include the Ebbinghaus-Titchener illusion, the Delboeuf illusion, and the Jastrow illusion (see Fig. 1). Understanding how humans, and other species, misperceive the world through

**Size Illusion, Fig. 1** Example of the Ebbinghaus-Titchener illusion (top), Delboeuf illusion (middle), and Jastrow illusion (bottom). For the Ebbinghaus-Titchener stimuli, most people believe the central dot at right (surrounded by small dots) is larger than the central dot at left (surrounded by large dots). For the Delboeuf illusion, most people believe the central dot at right is larger than at left. For the Jastrow illusion, most people believe the shape at bottom is larger than the one at top. In cases, those central dots or shapes are the same size

susceptibility to these and other illusions provides important insights into the nature of perception and also into the subsequent choice behavior and decision-making processes that rely on perceptual experiences. For this reason, perceptual illusions have been of great interest to psychologists, philosophers, and vision scientists, and discussions about the nature of illusory experiences stretch back to the ancient Greeks.

## Geometric Illusions: Misperceptions of Size

Geometric illusions emerge when the physical dimensions of a target stimulus are misperceived as a function of the illusory-inducing context in which it is presented. Geometric illusions can lead to misperceptions of size, length, height, color, perceived movement and direction and brightness. Specifically, size illusions emerge when the area of a target stimulus is misperceived to be larger or smaller than reality. Note that some people would also include other illusions in this broad category beyond those that we discuss, given that things such as size, length, and width can also be considered as subcategories of size. In that case, the Müller-Lyer illusion, Oppel-Kundt illusion, Baldwin illusion, vertical-horizontal illusion, Ponzo illusion, and others also could be included. Here, we have focused on illusions for which the judgment is to be made specifically on size, and not those other properties. For example, in the Ebbinghaus-Titchener illusion (hereafter Ebbinghaus illusion; Fig. 1), a central dot is misperceived as a function of the size of inducing circles, such that large inducers lead to underestimates of central dot size and small inducers lead to overestimates of central dot size. Scientific investigations of geometric illusions such as this one date back to the 1800s and continue to provide a noninvasive means by which psychologists can understand better the visual and perceptual systems of humans and animals.

A critical component underlying the emergence of geometric illusions concerns perceptual processing mode or the manner in which an individual perceives the global figure relative to the individual elements that comprise a visual array. For illusory experiences, the target stimulus is misperceived as it is viewed in conjunction with the illusory context (e.g., the Ebbinghaus central dot is perceived among the inducer circles). Species and even individuals within a species differ in terms of the readiness with which they perceptually group the individual elements within an array, with some displaying a global-to-local precedence (i.e., perception of the global configuration prior to the individual elements; central dot + inducers) and others a local-to-global

precedence (i.e., individuation of the separate elements prior to perception of the global figure; inducers and central dot separately). Regarding comparative investigations, species differ in their perceptual processing mode, thus visual illusions provide a useful means by which we can study potential differences in perceptual mechanisms using similar experimental procedures across a variety of settings and species.

Furthermore, geometric size illusions emerge as a function of contrast and assimilation mechanisms, which have received ample attention in comparative studies. Contrast effects result in overestimates of the difference between stimuli that are positioned farther apart, whereas assimilation effects result in underestimates of the difference between stimuli positioned nearby. Using the Delboeuf size illusion illustrated in Fig. 1, the central target dot is contrasted with the larger, distal ring and thus perceived as smaller than the central target dot with the smaller, nearby ring that it assimilates with leading to overestimates in target dot size. Species differences in susceptibility to contrast and assimilation effects have been documented for a variety of geometric illusions (e.g., the Ponzo and Müller-Lyer line-length illusions), with the most well-studied case of the pigeon, which appears to be susceptible to assimilation effects but not contrast effects (see Fujita 2006, for a review). Thus, size illusions offer a useful means by which comparative psychologists can explore further species differences in sensitivity to contrast and assimilation mechanisms.

### The Jastrow Illusion

A well-known size illusion experienced by humans is the Jastrow illusion (Fig. 1). In this case, two vertically stacked but offset stimuli of identical size are misperceived in such a way that the perceiver believes the bottom stimulus is larger than the top stimulus. Only three assessments of the Jastrow illusion have been conducted with nonhuman animals. Révész (1924) trained a hen to peck for grains from the relatively smaller of two objects placed in an arena where the size and shape of the objects varied throughout

training. Then, arenas were presented with two same size objects arranged in a Jastrow-like pattern. The hen showed a significant bias toward the object that was estimated as smaller by human observers (the top shape in Fig. 1). Tomonaga (2015) trained four chimpanzees to select a narrower stimulus from two options in a computerized size discrimination task. Then, the Jastrow-like illusory pair of stimuli were presented on some trials, and the chimpanzees selected the top stimulus more often than expected by chance, suggesting that they perceived the top stimulus as the narrower option. Finally, Agrillo et al. (2019) presented the same computerized task to human adults, rhesus macaques, and capuchin monkeys. All species learned to discriminate shapes based on size, and when presented with Jastrow illusion trials, humans perceived the illusory stimuli as predicted. Although both species of monkeys performed well in trials with a true size difference between shapes, they did not show evidence of the Jastrow illusion. They were indifferent between top and bottom stimuli in the illusory arrangement. This could lead to a prediction that broader species testing with this illusory condition also may produce highly varied results.

### The Ebbinghaus and Delboeuf Illusions

The Ebbinghaus and Delboeuf illusions are two of the most well-studied geometric size illusions represented in the human and animal literatures. In these illusions, a central target dot is misperceived as smaller when surrounded by larger inducing stimuli (Ebbinghaus inducer circles or Delboeuf ring) and larger when surrounded by smaller inducing stimuli due to assimilation and contrast mechanisms (Delboeuf 1892; Ebbinghaus 1902). A variety of species have been presented with the Ebbinghaus and Delboeuf illusions using two-dimensional stimuli as depicted in Fig. 1 via computerized or manual testing. Additionally, a number of studies have presented animals with a two-choice

discrimination procedure using edible food stimuli arranged in the shape of the illusory array. Control trials using either approach establish whether the subject can discriminate true differences in size in the absence of the illusory inducing context (e.g., discrimination of central target dots with no rings or identically sized rings). These trials are vital to determining whether subjects understand the objective of the size discrimination task and whether they are sensitive to certain discrimination thresholds at which the illusions are most likely to emerge. Critical test trials present the illusory inducing context (e.g., two different-sized rings surrounding nearly identical or identical dots) with the prediction that animals will classify or choose the target dot surrounded by a small context as larger than the target dot surrounded by a large context.

A number of species presented with the Ebbinghaus and Delboeuf illusions respond in a humanlike direction, perceiving stimuli surrounded by large inducers as being smaller and vice versa, including redbtail splitfin (Sovrano et al. 2015), damselfish (Fuss and Schluessel 2017), bearded dragons (Santacà et al. 2019), dolphins (Murayama et al. 2012), domestic cats (Szenczi et al. 2019), capuchin monkeys and rhesus macaques (Parrish et al. 2015), and chimpanzees (Parrish and Beran 2014). A number of these species also have been assessed for their perceptual processing mode and reveal a global precedence, including redbtail splitfin, dolphins, and chimpanzees. However, evidence of a reversed or weakened Ebbinghaus and Delboeuf illusion has been documented in some species, including guppies (Lucon-Xiccato et al. 2019), gray bamboo sharks (Fuss and Schluessel 2017), bantams and pigeons (Nakamura et al. 2008, 2014), domestic dogs (Byosiére et al. 2017; Miletto Petrazzini et al. 2017), lemurs (Santacà et al. 2017), and baboons (Parron and Fagot 2007). These cases may reveal a weakened susceptibility to contrast effects or a local precedence and, in some cases, an inability to discriminate size at a particular threshold necessary for illusory emergence.

Methodological variations also impact illusory emergence for animals and humans. Experimental designs that highlight the inducer or target stimuli as separate units undermine global processing in

humans, such that increasing the distance between stimuli or varying the brightness or shape of the inducer circles and target dot lead to a weakened Ebbinghaus illusion. For example, comparative studies yielding a weakened or reversed Ebbinghaus illusion employ methods that aid the animal in differentiating the target and inducer stimuli via different color/brightness stimuli (Nakamura et al. 2008, 2014; Parron and Fagot 2007). Studies have shown that a non-illusion or a reversed illusion may emerge when animals fail to differentiate target and inducer stimuli and inadvertently respond to the size of the overall array versus the target stimulus alone (e.g., Parrish et al. 2015; Qadri and Cook 2019).

Perceptual processing mode also appears to be linked to viewing angle, such that closer vantage points lead to a focus on local elements versus more distal vantage points which favor apprehension of the global array in human adults. Comparative studies have reported differences in the susceptibility to the Ebbinghaus illusion among the same species (the domestic chicken), with a study that required a pecking response to stimuli (and arguably a closer vantage point) leading to a reversed illusion (Nakamura et al. 2014). In contrast, a study that required domestic chicks to approach the stimuli from a distance (and arguably a more distal vantage point) reported evidence of a humanlike Ebbinghaus illusion (Rosa Salva et al. 2013). Thus, experimental design has clear impacts on the emergence of size illusions, such that methodological variations in training, stimuli design, and response modality likely interact with a species' perceptual processing mode to directly influence the emergence of illusory perceptions. Future studies with additional species would be illuminating and could lend empirical support for some of the theoretical ideas that have emerged from studies of these and other geometric illusions.

## Synonyms

Appendicular skeleton; Axial skeleton; Endoskeleton; Skeleton; Vertebrate skeleton

## Definition

The skeletal system refers to all structures, both rigid and semirigid, which provide structural foundation, support the body's soft tissues, protect internal organs, and provide necessary leverage for muscle function.

## Introduction

Skeletal systems may vary widely between species, but all serve to provide both functional structure and protection from external injury. For most insects, crustaceans, and other invertebrates, this structure is the outermost part of the body and is called an exoskeleton. In vertebrates, this structure is internal and is called an endoskeleton. Vertebrate skeletons are a group of relatively rigid structures composed of a combination of connective tissues generally classified as bone and cartilage (Encyclopedia Britannica 2018). This chapter will focus on the development, function, and anatomical specifics of the vertebrate skeletal system.

## Skeletal System Development

The skeletal system is comprised of mainly two types of connective tissue: bone and cartilage. Bones are a specialized form of connective tissue with a mineralized matrix and are generally considered the organs of the skeletal system. Their mineralized matrix, composed of hydroxyapatite crystals, results in the extremely hard structure of bones that allow them to provide support and protection (Ross and Pawlina 2006, p. 202).

Because bones tend to vary widely in terms of size, shape, structure, and even function, there are a number of ways in which bones can be classified. One classification system involves the structural arrangement of the bone tissue. Cancellous, or "spongy bone," refers to the latticelike trabeculae that form the innermost part of bones (Ross and Pawlina 2006, p. 203). In contrast, "compact bone" refers to the solid, dense layer that forms on the outside of bones. The periosteum is a sheet

of fibrous connective tissue that surrounds the outside of the bone (Zalisko and Kardong 2001, p. 40). Bones are also often characterized according to their shape. Long bones are elongated in one direction when compared to the other and are generally composed of a shaft and two ends. An example of a long bone would be a femur. Short bones are generally described as having a diameter that is equal in all dimensions, like the carpal bones of many species. Flat bones, like the sternum, are generally thin with a small layer of spongy bone sandwiched between two outer layers of thick compact bone. The final shape category is referred to as irregular bones. These bones have shapes that do not fit with the other three categories, like vertebrae (Ross and Pawlina 2006, p. 204).

Bones can also be classified according to embryologic origin. Different portions of the skeleton are generated by different developmental processes. The axial skeleton is derived from somites, the appendicular skeleton is a product of the lateral plate mesoderm, and the craniofacial bones are generated by the cranial neural crest (Gilbert 2000). The formation of the bone is generally classified by one of two processes.

Bones can form through either (a) endochondral ossification or through (b) intramembranous ossification. Endochondral ossification relies on a cartilaginous template as a bone precursor, where intramembranous ossification is the direct conversion of mesenchymal tissue into bone tissue (Gilbert 2000). Generally, bones that are weight bearing, like bones of the appendicular skeleton or the vertebral bones, are formed by endochondral ossification. In contrast, intramembranous bones form directly from the mesenchyme without a cartilage precursor. Sesamoid bones, periosteal bones, and dermal bones all undergo intramembranous ossification. Bones like the patella, portions of the skull, the clavicle, and even the turtle shells are formed by the direct bone formation method of intramembranous ossification (Gilbert 2000). Though the two methods may differ in their initial stages, the preliminary bone laid down by both methods is quickly replaced by identical new bone (Ross and Pawlina 2006, p. 216).

In endochondral (*endo*, within; and *chondral*, cartilage) bone formation, cartilage is a specialized connective tissue that is composed of chondrocytes and a significant extracellular matrix. Chondrocytes are specialized cells within cartilage that both produce and maintain the extracellular matrix (Ross and Pawlina 2006, p. 184). The avascular character of cartilage means that there is no blood flow through any cartilaginous tissues. This lack of vascular channels, vital for the cartilage cells survival, accounts for the dependence of the chondrocytes on the extensive extracellular matrix (Ross and Pawlina 2006, p. 182). Essential nutrients reach the chondrocytes via extensive diffusion from the blood vessels in the perichondrium through the matrix (Zalisko and Kardong 2001, p. 39).

Based on the type and amount of protein fibers that are present in the extracellular matrix, cartilage is further divided into three subcategories: hyaline cartilage, elastic cartilage, and fibrocartilage. Hyaline cartilage is the most common type of cartilage and is found in many places throughout the skeletal system (Zalisko and Kardong 2001, p. 40). The matrix of hyaline cartilage is produced by chondrocytes and contains type II collagen molecules, proteoglycans, and multi-adhesive glycoproteins. Hyaline cartilage serves a variety of functions and is found in both fetal and adult skeletons. During fetal development, the hyaline cartilage serves as the model for the developing skeleton. In initial stages of development, most long bones are represented by hyaline cartilage templates that resemble the shape of the eventual mature bone (Hill 2018). As development progresses, it is replaced by bone until cartilage remains only on articular surfaces of joints and on the ends of ribs. These cartilaginous structures persist in adulthood and provide a smooth, well-lubricated surface for the ends of bones within a joint. Hyaline cartilage is also found in the larynx, trachea, and bronchi of adults (Ross and Pawlina 2006, p. 194).

Elastic cartilage differs from the other types of cartilage due to the presence of elastin in the extracellular matrix. While elastic cartilage maintains the resilience and pliability of hyaline cartilage, the structure of its extracellular matrix gives

it additional properties of elasticity and flexibility. This type of cartilage is commonly found in the external ear, the auditory tube, and the epiglottis (Ross and Pawlina 2006, p. 190).

The last cartilage subtype, fibrocartilage, is hyaline cartilage that has been combined with dense connective tissue. It is histologically similar to hyaline cartilage, except for an increased number of collagen fibers present in fibrocartilage (Zalisko and Kardong 2001, p. 40). This type of cartilage is analogous to a shock absorber. It is often present in locations that require significant resistance to shearing and compressive forces. Fibrocartilage is present in intervertebral disks, the pubic symphysis, menisci, and occasionally at a given point of tendon insertion. It is composed of both type I and type II collagen and functions to resist distortion under stressors (Ross, p. 191).

## General Skeletal System Structure

The body's skeletal system can be subdivided into the axial skeleton and the appendicular skeleton (Pasquini et al. 2007). The term “axial skeleton” refers to the bones and cartilage that protect the soft tissue structures of the head, neck, thorax, and abdomen. These structures include the skull, the hyoid apparatus, the vertebral column, the ribs, and the sternum (Pasquini, p. 26).

### The Axial Skeleton

#### Cranial Skeleton (Skull)

The size and shapes of vertebrate skulls may differ drastically between different animals, but a common morphological pattern to the bones and their locations exist between most vertebrate species. The dorsal portion of the skull incorporates the frontal bones and the parietal bones, which together form most of the dorsal covering of the cranial cavity. The occipital bones occupy a large portion of the back of the skull and include the paired occipital condyles and the foramen magnum. A lateral view of the skull shows the upper portion of the jaw, or the maxilla, articulating with the lower jaw bone, the mandible. The temporal process of the zygomatic bone and the zygomatic

process of the temporal bone join together to form the zygomatic arch. Caudal to the maxilla and just below the zygomatic arch lay the palatine bone, the presphenoid, and the basisphenoid. The hard palate of the skull is formed by the palatine processes of the premaxillae, the maxillae, and the palatine bones.

### Vertebral Column

The vertebral column, or the backbone, is the main phylogenetic trait of all vertebrate species. While basic structural aspects of the vertebral column can differ between species, general trends in development, structure, and function can be seen across all vertebrates. The mammalian vertebral column can be broken down into five different areas or subsections: cervical vertebrae, thoracic vertebrae, lumbar vertebrae, sacral vertebrae, and caudal vertebrae. Segments of fibrous cartilage are located between the bony vertebrae and are known as intervertebral disks (Zalisko and Kardong 2001, p. 53).

### Cervical Vertebrae

In mammals, the first two cervical vertebrae are referred to as the atlas and the axis. The atlas is a ring-shaped vertebra with paired, winglike transverse processes. The axis sits just caudal to the atlas and has a broad spinous process that projects over the atlas. In most mammals, the axis would be followed by five additional vertebrae with articular processes, vertebral foramen, a neural arch, a spinous process, centrum, and transverse processes (Zalisko and Kardong 2001, p. 52).

### Thoracic Vertebrae

The thoracic vertebrae of mammals are generally tall with short transverse processes and spinous processes angled caudally. There is a small depression where the head of the rib articulates with the centrum known as the facet.

### Lumbar Vertebrae

Lumbar vertebrae can be differentiated from thoracic vertebrae based on the cranial orientation of the transverse and spinous processes (Zalisko and Kardong 2001, p. 52).

### Sacral Vertebrae

In mammals, the individual sacral vertebrae are fused together to form a single sacrum. The number of fused sacral vertebrae differs between species. There are three fused vertebrae in dogs and cats, four in a rabbit, and five in humans and horses (Zalisko and Kardong 2001, p. 52).

### Caudal Vertebrae

The transition to the caudal vertebrae is accompanied by a significant loss in prominence of the arches and processes. The number of caudal vertebrae is dependent on tail length, and there is significant difference between species and even individuals. In humans, all caudal vertebrae fuse together into a single piece called the coccyx (Zalisko and Kardong 2001, p. 52).

### Ribs (Costae)

Ribs are comprised of a bony vertebral rib and costal cartilage. Ribs are bicipital, with the capitulum, or head of the rib, articulating with the centrum and the tubercle articulating with the transverse process. The bony portion between the capitulum and the tubercle is called the neck, and the rest of the rib is referred to as the body or shaft (Zalisko and Kardong 2001, p. 52).

### Sternum

The sternum, also sometimes referred to as the breastplate, is a flat bone composed of usually eight sternebrae that attach to the ventral aspects of the ribs. The first and most cranial sternebra is called the manubrium, and the most distal sternebra is called the xiphoid. Six additional sternebrae lie in between the manubrium and the xiphoid making up the body of the sternum.

## The Appendicular Skeleton

The term “appendicular skeleton” includes limb bones as well as the bones that connect the limbs to the axial skeleton (Pasquini et al. 2007, p. 26).

### Pectoral Girdle

For the majority of mammalian species, the pectoral girdle is characterized by significant mobility as well as structural support. Because of its intrinsic mobility, the thoracic girdle has an increased

reliance on surrounding musculature for proper support and appropriate transmission of forces. The mammalian pectoral girdle generally only includes a clavicle and scapula. The paired clavicles serve to anchor the thoracic limbs to the axial skeleton. The scapula is a flat bone located on the dorsal portion of the cranial thorax that serves as an attachment point for many of the muscles and tendons of the arm, chest, and back. Each scapula has a spine that terminates in a point called the acromion. The acromion process articulates with its respective clavicle serving as the attachment point for muscles of the arm and chest (Pasquini, p. 26).

#### Thoracic Limbs

The humerus is the largest forelimb bone. The proximal head of the humerus articulates with the glenoid cavity of the scapula to create the shoulder joint. Two processes, known as the greater and lesser tubercles, are present distal to the humeral head and neck. These serve as attachment points for important forelimb musculature. The body of the humerus terminates into the medial articular surface called the trochlea and the lateral articular surface called the capitulum. The distal portion of the humerus articulates with the proximal portion of the forearm bones to form the elbow joint. The trochlear notch of the ulna articulates with the trochlear surface of the humerus. The head of the radius articulates with the capitulum of the humerus. The distal ends of the radius and ulna articulate with multiple carpal bones to form the wrist joint. The five metacarpals and phalanges make up each hand and its digits (Pasquini, p. 72).

#### Pelvic Girdle

When compared to the pectoral girdle, the bones of the pelvic girdle tend to be solid and fixed weight bearing structures. Its structure provides strong foundational stability and support for movement. The fused bones of the ilium, acetabulum, ischium, and pubis make up the hemipelvis (Evans and de Lahunta 2010, p.81). The ilium is comprised of a narrow body and a concave wing. The acetabulum is a socket that
